

A MEMETICS COMPENDIUM

Compiled By

Dr. Robert Finkelstein

President, Robotic Technology Inc.

Collegiate Professor, University Of Maryland University College

Office: 301-983-4194

Prepared for Dr. Amy Kruse

Defense Advanced Research Projects Agency

Task Order: CA-FIN-3212-024-08

SA Prime Contract: NBCHC020019

May 2008

CONTENTS

(Note: Some of the papers have been edited for grammar, spelling, format, and clarity)

COMPENDIUM INTRODUCTION: MILITARY MEMETICS OVERVIEW Robert Finkelstein	12
COMPENDIUM EXCERPTS Robert Finkelstein	21
CRITIQUE AND DEFENSE OF MEMESIS Onar Aam	58
MEMETICS AND MONTAG B. Antomarini, et. al.	63
DO MEMES ACCOUNT FOR CULTURE? Robert Aunger	69
CULTURAL EVOLUTION OF “GUIDING CRITERIA” Gianluca Baldassarre	78
MEMESIS CRITIQUE Richard Barbrook	95
MEMETIC MEANINGS Francis A. Beer	100
MODELS FOR INTERACTING POPULATIONS OF MEMES Michael L. Best	104
A CRITIQUE OF MEMETIC MODELS Michael L. Best	122
THE LIFECYCLE OF MEMES Henrik Bjarneskans, et. al.	127
MEMES, MINDS, AND SELVES Susan Blackmore	148
WAKING FROM THE MEME DREAM Susan Blackmore	160
IMITATION AND THE DEFINITION OF A MEME Susan Blackmore	170
THE FORGET-MEME-NOT THEORY Susan Blackmore	182
THE POWER OF THE MEME MEME Susan Blackmore	186
THE EVOLUTIONARY ECOLOGY OF SCIENCE Marion Blute	201
MEMETICS AND EVOLUTIONARY SOCIAL SCIENCE Marion Blute	223
CONSTRUCTION OF IGNORANCE, EVOLUTION OF KNOWLEDGE P. Bouissac	227
EDITORIAL: MEMES MATTER Paul Bouissac	241
WHY DO MEMES DIE? Paul Bouissac	248
THE HUMAN AGENCY OF MEME MACHINES Gary Boyd	256
INTRODUCTION TO THE CRISIS OF THE MIND Richard Brodie	264
THE MEME HUNTER Andrew Brown	271
MINIMAL REQUIREMENTS FOR DARWINIAN BOOTSTRAPING William H. Calvin	275
TOWARDS A COGNITIVE MEMETICS Cristiano Castelfranchi	286

HOW (UN) REALISTIC ARE EVOLUTIONARY ALGORITHMS Edmund Chattoe	311
VIRTUAL URBAN LEGENDS Edmund Chattoe	355
PARASITE ECOLOGY AND THE EVOLUTION OF RELIGION Ben Cullen	372
CHAPTER 11 FROM “THE SELFISH GENE” Richard Dawkins	378
SURVIVAL OF THE INSTITUTIONALLY FITTEST CONCEPTS Martin de Jong	394
MEMES AND THE EXPLOITATION OF IMAGINATION Daniel Dennett	414
MEMES: MYTHS, MISUNDERSTANDINGS, AND MISGIVINGS Daniel C. Dennett	427
THE EVOLUTION OF CULTURE Daniel C. Dennett	438
COMPETING MEMES ANALYSES David K. Dirlam	451
USING MEMETICS TO GROW MEMETICS David K. Dirlam	461
SIMULATING COLLECTIVE MISBELIEF Jim Doran	469
THE REVEALED POVERTY OF THE GENE-MEME ANALOGY Bruce Edmonds	483
THE EVOLUTION OF LANGUAGE AND SCIENCE Börje Ekstig	486
A JUSTIFICATION OF SOCIETAL ALTRUISM John R. Evers	500
STROLLING THROUGH THE MEMETIC MINE FIELD Leon Felkins	506
VIRAL MARKETING: SPREAD A COLD, CATCH A CUSTOMER Frank Fiore	519
CULTURAL R/K SELECTION Agner Fog	522
APPLYING MEMETICS TO FINANCIAL MARKETS Joshua Frank	538
A COMPUTATIONAL MODEL OF CULTURAL EVOLUTION Liane M. Gabora	550
A DAY IN THE LIFE OF A MEME Liane Gabora	558
MEMES: THE CREATIVE SPARK Liane M. Gabora	590
THE ORIGIN AND EVOLUTION OF CULTURE AND CREATIVITY Liane Gabora	592
A TENTATIVE SCENARIO FOR THE ORIGIN OF CULTURE Liane Gabora	623
REVIEW OF THE MEME MACHINE Liane Gabora	649
MACROMEMETICS Derek Gatherer	655
“THOUGHT CONTAGION” METAPHOR IS RETARDING PROGRESS Derek Gatherer	673
THE CASE FOR COMMENTARY Derek Gatherer	698
A PLEA FOR METHODOLOGICAL DARWINISM Derek Gatherer	700

REPLY TO COMMENTARIES ON MY PAPER Derek Gatherer	703
MODELING MEMETIC TABOOS ON GENETIC HOMOSEXUALITY Derek Gatherer	709
THE SPREAD OF IRRATIONAL BEHAVIORS BY CONTAGION Derek Gatherer	727
FINDING A NICHE FOR MEMETICS IN THE 21ST CENTURY Derek Gatherer	748
THE INHERENT INSTABILITY OF MEMETIC SYSTEMS Derek Gatherer	754
MEMES AND ORGANIZATIONAL STRUCTURES Hélène Giroux et. al.	776
THEISTIC MEMES IN RELIGIOUS CANONS John D. Gottsch	783
MEMES: INTRODUCTION Glenn Grant	818
MEMETIC LEXICON Glenn Grant	820
MEMES AND THE CREATION OF DANCE Christine Greiner	826
MEMES AND GRINNING IDIOT PRESS Grinning Idiot Press 1993	829

INTRODUCTION to the COMPENDIUM and a MILITARY MEMETICS OVERVIEW

**By
Robert Finkelstein
Robotic Technology Inc.**

PURPOSE

The purpose of this Compendium is to provide a broad overview of memetics based on a variety of papers by various authors. These digital papers were gathered from the Internet during 2006 to 2008, assembled, and, in some cases, edited for grammar, spelling, and clarity; all of the papers were transformed into a common format (font, font size, appearance) for coherence to ease reading. The compendium was developed as part of memetics research conducted for the Defense Advanced Research Projects Agency (DARPA).

In the more than 30 years since the meme was identified as an entity of interest, there has been almost no research to determine whether memetics can be placed on a scientific basis so that its phenomena and effects can be quantified, predicted, and controlled. Most of the research of memetics, such as it is, has been conducted in scattered efforts, often as personal projects on the part of dedicated academics, mostly outside the U.S. There have been no significant, coherent efforts until now, where DARPA is exploring whether a scientific framework can be established for memetics.

The papers were selected subjectively, based on their perceived relevance to the subject and interest to the reader. For the ease of locating papers in the Compendium, they are arranged alphabetically by author, rather than topic.

Following this Introduction is a section of Compendium Excerpts, with passages I subjectively extracted from the papers based on what I thought might be of interest to the memetics project. The excerpts are alphabetical, by author, so the original complete text can be found easily in the Compendium by readers interested in a particular passage.

A separate volume includes articles and papers which are relevant to memetics but are not directly about memetics.

The purpose of the following overview is to provide an indication of the prospective value of memetics to the U.S. military for conventional and asymmetric operations, including counter-terrorism.

The attempt to establish a scientific basis for memetics is critically important. For example, within a suitable memetics framework could be the means to prevent irrational conflict and promote rational solutions to endemic national and international problems. Of course, without safeguards memetics can become a double-edged sword.

THE MEME

The word “meme” is a neologism coined by Richard Dawkins in *The Selfish Gene* (1976), (although it may have had earlier roots) and defined as a self-reproducing and propagating information structure analogous to a gene in biology. Dawkins focused on the meme as a replicator, analogous to the gene, able to affect human evolution through the evolutionary algorithm of variation, replication, and differential fitness. But for near-term military or national security applications, the relevant characteristics of the meme are that it consists of information which persists, propagates, and influences human behavior.

Meme Definitions

There are a plethora of definitions for the meme, with most being variations of Dawkins original notion of a unit (whatever that means) of cultural transmission, where culture may be defined as the total pattern of behavior (and its products) of a population of agents, embodied in thought, behavior, and artifacts, dependent upon the capacity for learning and transmitting knowledge to succeeding generations. None of extant definitions of a meme is sufficient to allow a meme to be clearly recognized, measured, or provide the basis for scientific research. And without the establishment of a scientific basis and the ability to explain, predict, and control phenomena, memetics will remain a functionally useless pseudo-science. A few of the many definitions extracted from the literature include:

- A self-reproducing and propagating information structure analogous to a gene in biology
- A unit of cultural transmission (or a unit of imitation) that is a replicator that propagates in the meme pool leaping from brain to brain via (in a broad sense) imitation; examples: “tunes, ideas, catch-phrases, clothes fashions, ways of making pots or of building arches”
- Ideas that program for their own retransmission or propagation
- Actively contagious ideas or thoughts
- Shared elements of a culture learned through imitation from others – with culture being defined rather broadly to include ideas, behaviors, and physical objects
- An element of a culture that may be considered to be passed on by non-genetic means, especially imitation
- Information patterns infecting human minds
- While the internal meme is equivalent to the genotype, its expression in behavior (or the way it affects things in its environment) is its phenotype
- Any information that is copied from person to person or between books, computers, or other storage devices. Many mental contents are not memes because they are not

acquired by imitation or copying, including perceptions, visual memories, and emotional feelings. Skills or knowledge acquired by ordinary learning are not memes

- A (cognitive) information-structure able to replicate using human hosts and to influence their behavior to promote replication
- Cultural information units that are the smallest elements that replicate themselves with reliability and fecundity
- A rule of behavior, encoded by functional neuronal groups or pathways. [Behavior is action, whether mental or physical. Ideas such as tying shoe-laces or opening a door represent rules of physical action, i.e., rules of patterned neural-muscular interaction. Concepts such as apple, seven, or causality, represent rules of mental action, or rules of cognition, i.e., rules of patterned neural-neural interaction. Hence, physical movement is governed by memes which represent rules of physical action and thought is governed by memes which represent rules of mental action]
- Any kind, amount, and configuration of information in culture that shows both variation and coherent transmission
- A pattern of information (a state within a space of possible states)]
- A unit of cultural information as it is represented in the brain
- An observable cultural phenomenon, such as a behavior, artifact or an objective piece of information, which is copied, imitated or learned, and thus may replicate within a cultural system. Objective information includes instructions, norms, rules, institutions and social practices provided they are observable
- A pattern of information, one that happens to have evolved a form which induces people to repeat that pattern
- A contagious information pattern that replicates by parasitically infecting human minds and altering their behavior, causing them to propagate the pattern. Individual slogans, catch-phrases, melodies, icons, inventions, and fashions are typical memes. An idea or information pattern is not a meme until it causes someone to replicate it, to repeat it to someone else. All transmitted knowledge is memetic
- The smallest idea that can copy itself while remaining self contained and intact – essentially sets of instructions that can be followed to produce behavior

While Dawkins focused on the meme as a replicator, analogous to the gene, able to affect human evolution through the evolutionary algorithm of variation, replication, and differential fitness, for near-term practical applications the relevant key characteristics of the meme are that it consists of information which persists, propagates, and influences human behavior.

We developed a pragmatic definition to distinguish a meme from other sorts of information (such as common daily utterances):

A meme is information which propagates, persists, and has impact.

To distinguish memes from other kinds of information, an elaboration of the definition invokes a threshold for propagation and persistence and employs Shannon's definition of *information as that which reduces uncertainty*. Impact might take place in the individual, in terms of neurophysiological changes (e.g., as detected by a brain scan) or manifestations of behavior; or it might take place in society (groups of individuals) as manifested by behavior. Metrics are defined (each with submetrics) to facilitate the measurement and comparison of memes. Additional metrics may be defined based on the results of future experiments with tools such as functional magnetic resonance imaging (fMRI). Other experimental approaches include the modeling and simulation of social networks and information propagation through social networks, as well as the tools and techniques of neuroeconomics.

As a practical approach, the metrics we initially defined for evaluating memes, as shown in Figure 1, include: propagation, persistence, impact, and entropy. The submetrics for the *propagation* metric include the number, type, and dispersion of recipients of the meme. Depending on the problem under consideration, the type of recipients might be characterized or categorized by their economic, social, or educational class, ethnicity or culture, religion, gender, age, tribe, politics, etc., while the dispersion of recipients might be categorized as local, tribal, familial, regional, national, global, etc. The submetrics for the *persistence* metric distinguish between the duration of transmission of the meme and the duration of the meme in memory or storage. The submetrics for the *entropy* metric distinguish among small, medium, and large memes, which (using an order of magnitude rule) are characterized as less than or equal to 100K bits, less than or equal to 100M bits, and greater than 100M bits. Submetrics for the *impact* metric distinguish between the impact (or potential impact) of the meme on the individual (i.e., individual consequence) and its impact (or potential impact) on society as a whole (i.e., societal consequence). For the initial exercises, we used a multivariate decision tool – the Analytic Hierarchy Process (AHP) – to weight the metrics and submetrics. This definition of the meme may be modified as the research progresses. A paper, not included in this Compendium, discusses our definition and its application in detail. In the paper we also develop an equation for a characteristic Memetic Fitness. Our definition of meme and derivation of memetic fitness are intended to elicit comment and suggestions for improvement.

Meme Transmission

As shown in Figure 2 (which replicates Claude Shannon's iconic schematic of a general communications system), a meme is transmitted after either being created in the mind of an individual or re-transmitted after being received by an individual from elsewhere. Arriving at a new potential host, the meme is received and decoded. The potential host becomes an actual host if the meme satisfies certain selection and fitness criteria. The new host replicates and transmits the meme (perhaps with a different vector, such as a text message instead of speech). Because the number of memes at any given time typically exceeds the number of recipients able to absorb them, fitness criteria determine which memes will survive, propagate, persist, and have

impact. The selection and fitness criteria include such human motivators as fear (e.g., of going to hell or failing in business) and reward (e.g., of going to heaven or succeeding in business); or the meme might be beneficial in a practical way (such as instruction on how to make a hard-boiled egg or an improvised explosive device); or the meme might be entertaining to the recipient, such as a joke (“why did the terrorist cross the road?”) or a song (“you can’t always get what you want”), or consist of appreciative direct feedback to the recipient (such as providing emotional satisfaction, e.g., reinforcement and pride in membership in a nation, tribe, religion, ethnic group, or ideology).

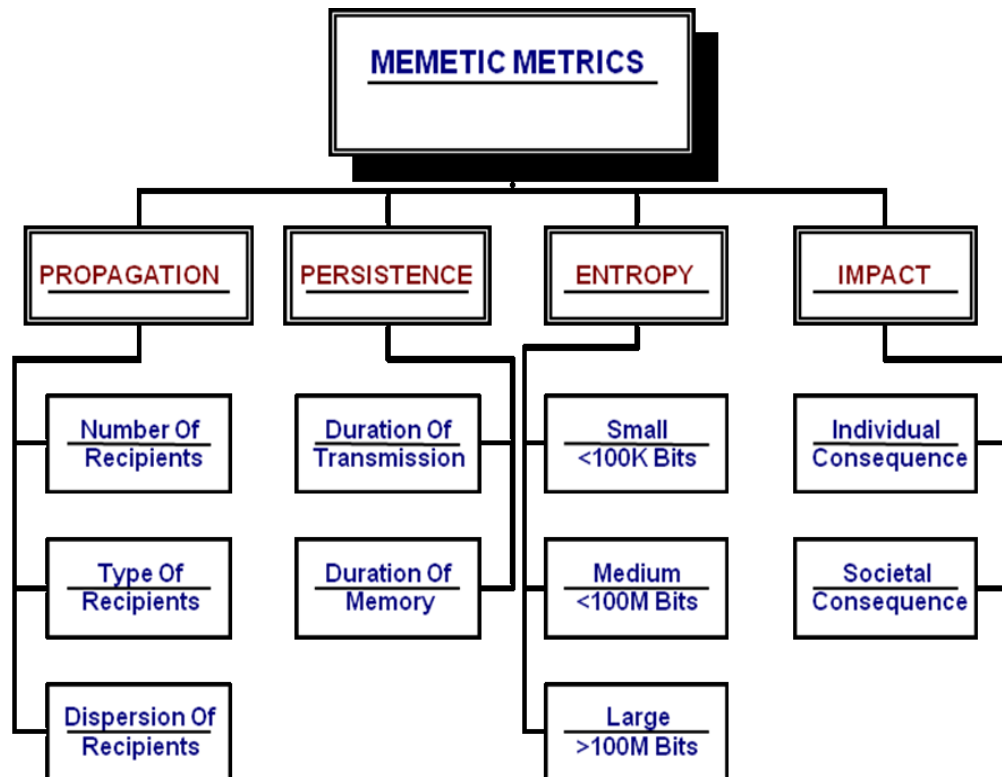

Figure 1: Memetic Metrics and Submetrics

To be readily acceptable to the host, the meme should fit existing constructs or belief systems of the host, or be a paradigm to which the host is receptive. Memes also aggregate and reinforce in complexes (memeplexes) so that a suitable existing framework in the mind of the host is especially susceptible to a new meme which fits the framework (such as a new precept by a religious leader being absorbed by a follower of that religion, whereas it would be ignored or escape notice by a non-follower). Suitable storage capacity, in memory or media, is necessary for the meme to persist, along with enduring vectors (e.g., the meme is literally chiseled in stone (such as the Rosetta stone) or reproduced in many, widely distributed copies of books or electronic media).

New research projects could provide a scientific and quantitative basis for memetics and an exploration of its prospective applicability and value, possibly discovering whether brief memes

such as “Death to America” or “Glory to the Martyrs” or “Winston tastes good like a cigarette should” are, in fact, cognitively and functionally different from non-memes such as “I like your hair,” or “please pass the salt”.

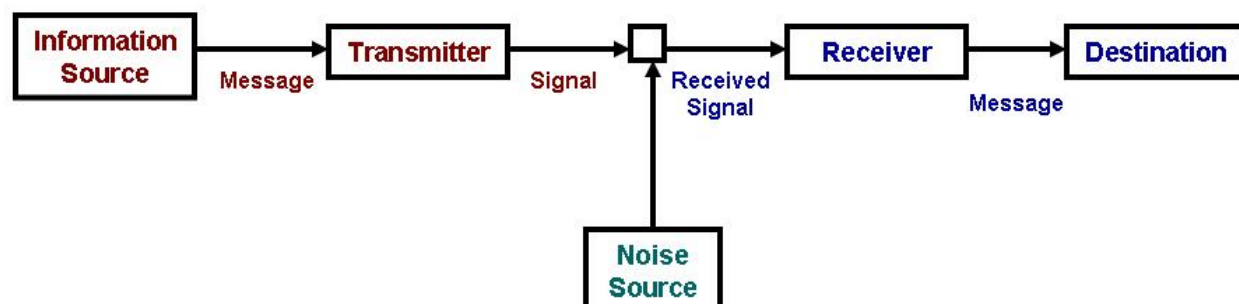

Figure 2: Meme Transmission Replicates Claude Shannon’s Iconic Schematic of a General Communications System

Quantitative Basis

Since Dawkins’ revelation about memes, the concept has attracted a coterie of proponents, skeptics, and opponents. In more than thirty years there has been no significant research of the concept to establish a scientific basis for it – but neither has there been a definitive refutation. To progress as a discipline with useful applications, memetics needs a general theory – a theoretical foundation for development of a scientific discipline of memetics. It needs a narrowly-focused, pragmatically-useful definition, and, ultimately, the ability to make testable predictions and falsifiable hypotheses. The discrete meme must be defined, identified, and distinguished in the near-continuum of information, just as the discrete gene can be identified (more or less) in long string of DNA nucleotides (albeit, with current technology a gene may not be clearly identifiable). A quantitative basis for memes must be established, using, for example, such tools as information theory and entropy; genetic, memetic, and evolutionary algorithms; neuroeconomics tools such as functional magnetic resonance imaging (fMRI) and biochemical analyses; and modeling and simulation of social networks and information propagation and impact.

Military Worth

If memetics can be established as a scientific discipline, its potential military worth includes applications involving information operations to counter adversarial memes and reduce the number of prospective adversaries while reducing antagonism in the adversary’s military and civilian culture, i.e., it could have the ability to reduce the probability of war or defeat while increasing the probability of peace or victory.

In the context of asymmetric or irregular warfare, information operations (IO) are of increasing importance for achieving victory (or avoiding defeat). Information operations consist of the integrated employment of the core capabilities of: electronic warfare, computer network operations, psychological operations, military deception, public affairs, and operations security. In concert with specified supporting and related capabilities, IO are deployed to influence, disrupt, corrupt or usurp adversarial human and automated decision making while protecting one's own. Potentially, memetics can have a major effect on psychological operations, military deception, and public affairs.

Psychological operations (PSYOP) are intended to induce or reinforce foreign attitudes and behavior favorable to the originator's objectives and to convey selected information and indicators to foreign audiences to influence their emotions, motives, objective reasoning, and ultimately the behavior of foreign governments, organizations, groups, and individuals. PSYOP focuses on the cognitive domain of the battlespace and targets the mind of the adversary. It seeks to induce, influence, or reinforce the perceptions, attitudes, reasoning, and behavior of foreign leaders, groups, and organizations in a manner favorable to friendly national and military objectives. It exploits the psychological vulnerabilities of hostile forces to create fear, confusion, and paralysis, thus undermining their morale and fighting spirit.

There are strategic, operational, and tactical PSYOP, as described in Joint Publication 3.53, *Doctrine for Joint Psychological Operations* (5 September 2003). Strategic PSYOP consists of international activities conducted by US Government agencies primarily outside the military arena but which may use DOD assets. Operational PSYOP is conducted across the range of military operations, including during peacetime, in a defined operational area to promote the effectiveness of the joint force commander's campaigns and strategies. Tactical PSYOP is conducted in the area assigned to a tactical commander, for a range of military operations, to support the tactical mission.

Psychological operations may occur across the spectrum of peace to conflict to war, integral to diplomacy, economic warfare, and military action, from negotiations and humanitarian assistance to counterterrorism. But according to *Information Operations Roadmap*, DOD (30 Oct. 03), despite PSYOP being a low-density, high-demand asset which is particularly valued in the war on terrorism, PSYOP capabilities have deteriorated. Well-documented PSYOP limitations include: an inability to rapidly generate and immediately disseminate sophisticated, commercial-quality products targeted against diverse audiences, as well as a limited ability to disseminate PSYOP products into denied areas. Remedial action is urgently required – and memetics may be a solution to recent PSYOP difficulties.

Military deception (MILDEC) involves actions executed to deliberately mislead the adversary's military decision makers about friendly military capabilities, intentions, and operations, thereby causing the adversary to take specific actions (or inactions) that will contribute to the accomplishment of the friendly force's mission. According to *Information Operations Roadmap*, DOD (30 Oct. 03), military deception should be one of the five core capabilities of IO and the value of military deception is intuitive. Counter-propaganda includes activities to identify and counter adversary propaganda and expose adversary attempts to influence friendly populations and military forces situational understanding. It focuses on efforts to negate,

neutralize, diminish the effects of, or gain an advantage from foreign psychological operations or propaganda efforts.

Public Affairs Operations (PA) assess the information environment in areas such as public opinion and attempt to recognize political, social, and cultural shifts. PA is a key component of information-based flexible deterrent options, intended to build the commanders' predictive awareness of the international public information environment and the means to use information to take offensive and preemptive defensive actions. PA is considered to be a lead activity and the first line of defense against adversary propaganda and disinformation (with the caveat that it must never be used to mislead the public, national leaders or the media). According to Field Manual FM 46-1, *Public Affairs Operations* (HQ, Department of the Army, Washington, DC, 30 May 1997), public affairs operations are combat multipliers in that they keep soldiers informed, maintain public support for the soldier in the field, and mitigate the impact of misinformation and propaganda.

Memetics also has potential military worth in supporting the military culture by enhancing recruitment and training. Recruitment may be improved with memetics by influencing the motivation of prospective recruits, enhancing the image of the military, increasing service awareness ("branding"), providing a national perspective and global situational context for serving one's country. Likewise, training can be improved by increasing trainee motivation, providing better explanations for the training, easing comprehension of the training components, enhancing retention of what is learned during training, and solidifying military culture for the trainees (traditions, customs, and mores).

Prospects

Memetics can mitigate unfavorable consequences from an adversary's culture and help to deter conflict and reduce animosity through cultural education and generating acceptable solutions to endemic problems. In the case of combat, memetics can enhance tactics, strategy and doctrine by making an otherwise adversarial situation more acceptable to non-combatants, helping to minimize collateral damage by improving the ability to discern combatants from non-combatants, and encouraging civilians to identify insurgents and terrorists. At the conclusion of combat, memetics can bolster peacekeeping, occupation, and nation-building by making these operations more palatable to civilians and facilitating patience for the "long-haul." During post-combat with continuing insurgence, memetics can help minimize collateral damage by enhancing the ability to discern combatants from civilians and identify insurgents and terrorists.

COMPENDIUM EXCERPTS

Subjectively Excerpted By
Robert Finkelstein

Based on What Might Be of Interest to the Project
May 2008

CRITIQUE AND DEFENSE OF MEMESIS, By Onar Aam, May 1996

- As a scientist who have been working a lot with these ideas I feel competent to outline a sparse list of fields which memetics should be developed upon: behaviorist sciences, phenomenology, communication theory, systems theory, Artificial Sociality (ASoc) and cognitive sciences. This list is far from complete, but it illustrates the diversity that is required to turn memetics into a science
- If you ask a geneticist what a gene is he can give you a quite elaborate technical definition. If you however ask a memeticist what a meme is she can give you a lot of examples, but no coherent definition.
- Information -- or rather culturally transmitted information -- is therefore the substance which memes are made of. This is how far traditional memetic ontology extends.
- Now, if the meme-concept is to have any scientific meaning whatsoever there must exist a consistent method of measurement.
- A taxonomy for memes does not exist.
- Another serious problem is what role consciousness plays in memetics.
- Hence measuring ideas is virtually impossible with current behaviorist methodology.
- Thus, the problem that memetics has to deal with greatly resembles that of nurture vs. nature. I.e. is the behavior of people environmentally encoded (i.e. cultural transmitted) or is it biological (i.e. emergent)? The answer is yes! (i.e., both).
- A culture with a superior technology also has the power to take over other cultures. The other cultures have two options: 1) surrender and perish, or 2) adapt to the technology of the enemy and survive. Since history is written by the survivors history is full of arms races, and in the long run the only winner is technology. As such we are undeniably slaves of technology whether we like it or not.
- As of today memetics is very far from fulfilling the requirements of a science. But I think it is just a matter of time before most of these problems have been resolved.

A REPORT ON THE CONFERENCE: “DO MEMES ACCOUNT FOR CULTURE?” By Robert Aunger

- The possibility that it is behaviors rather than ideas which replicate was not specifically considered, although that is a position adopted by others within the memetics community (e.g., Derek Gatherer, William Benson). David Hull forcefully argued, however, that definitional uncertainties should not stand in the way of progress; it certainly did not in the case of genetics during the first part of this century.
- It was argued that memes can certainly influence genetic evolution. One need only think of lactose intolerance (an example discussed by Kevin Laland), where cultural practices (such as drinking milk) influence gene frequencies in a group. Likewise, genes may determine meme frequencies, if indirectly, through psychological biases against the adoption of some kinds of beliefs or values. The general consensus was that both replicators should be seen as coevolving in potentially complex ways.
- As parts of the brain, memes are intimately involved in highly distributed, highly structured and interconnected networks of neurons. Therefore, the means by which they are stored and evoked are highly contextualized. So, memes spend most of their time as parts of streams of thought which are continuously renewing, revising, and reassessing the constituent memes. It is the analysis of these more holistic streams of information which should be our primary focus. This can be accomplished.
- Initially, Richard Dawkins argued it was important to consider the evolution of memplexes such as religious doctrines. What happens if some component of the complex is missing? Does its ability to function degrade significantly?
- Another major set of issues concerns the psychology of memes. The question which dominated discussion in this workshop is whether memetics can proceed without a clear idea of what kinds of transformations memes undergo during storage and retrieval by brains. Can memetics leave the brain as a black box, and deal only with social transmission aspects?
- It was also remarked that there is a problem of circularity in the way memetics is generally conducted. Memeticists only study things which seem likely to follow a memetic process, like fashions and fads (e.g., the infamous backward baseball cap). The perceived success of such empirical adventures leads memeticists to self-congratulation. But many aspects of culture aren't small, isolatable bits of information or practices that readily diffuse in observable time. Take the example of language, which permeates every aspect of culture. How does memetics expect to explain these more fundamental components of culture?
- The word "meme" itself has problems. Its close parallel to "gene" may lead memetics astray, if in fact memes are not the same kind of thing.

- A general disappointment was the lack of discussion about what might be called "applied memetics." More time certainly needs to be devoted in future to thinking of ways to do memetics.

CULTURAL EVOLUTION OF “GUIDING CRITERIA” AND BEHAVIOR IN A POPULATION OF NEURAL NETWORK AGENTS, By Gianluca Baldassarre

- An important form of cultural evolution involves individual learning of behavior by the members of a population of agents and cultural transmission of learned behavior to the following generations. The selection of behaviors generated in the process of individual learning requires some "guiding criteria".
- Culture can be defined as the total pattern of behavior (and its products) of a population of agents, embodied in thought, action and artifacts, and dependent upon the capacity for learning and transmitting knowledge to succeeding generations.
- "Direct bias" implies that the descendants directly test (some of) the cultural traits present in the population, and adopt the best ones. "Indirect bias" implies that the descendants adopt the cultural traits of the most successful individuals, while "frequency bias" implies that the descendants adopt the cultural traits with the highest frequency within the population. Finally "guided variation" implies that the behavior is transmitted by one generation to the other ("cultural transmission") and that the agents in the new generation go through a process of individual learning that modifies the acquired behavior before transmitting it to the next generation. Guided variation leads to the evolutionary emergence of new behaviors in the population ("cultural evolution") in a Lamarckian-like fashion.

MEMETIC MEANINGS – A COMMENTARY ON ROSE’S PAPER: CONTROVERSIES IN MEME THEORY, By Francis A. Beer

- Memes may be like genes in certain ways, but they cannot be identical if only because of the differences between physical and cultural phenomena.
- The Darwinian theory of evolution was itself a memetic adaptation.
- 'Mind' has different meanings in biological, psychological, linguistic, and philosophical contexts.

LETTER ON: MEMES ON MEMES – A CRITIQUE OF MEMETIC MODELS, By Michael L. Best

- I hold building a science of memetics as an admirable project. Slow progress towards such a science has been made as evidenced by much of the cited literature.

- It is best to test formal models on real empirical data. In this way predictions can be verified, fit can be measured, hypotheses can be tested. Sadly, empirical data is not always available. Alternatively, computational simulation and analysis can act as a surrogate for empirical data.

THE LIFECYCLE OF MEMES, By Henrik Bjarneskans, Bjarne Grønnevik and Anders Sandberg

- Memes, self reproducing mental information structures analogous to genes in biology, can be seen as the basis for an explanatory model of cultural and psychological behavior.
- Memes were originally described by Richard Dawkins in his book *The Selfish Gene* (1976): *A unit of cultural transmission or a unit of imitation.*
- What makes the meme concept so powerful is its close analogies to the theory of natural selection. Natural selection occurs whenever the following conditions exist (Dennet 1990):
 - Variation: a continuing abundance of different elements.
 - Heredity or replication: the elements have the capacity of creating copies or replicas of themselves.
 - Differential "fitness": the number of copies of an element that are created in a given time varies, depending on the interaction between the features of that element (whatever it is that makes it different from other elements) and features of the environment in which it persists.
- Although people often make the decision to spread a meme or not consciously, this process is influenced by the meme. Some memes are viewed as important, and hence spread to others after a conscious and sometimes rational evaluation; some memes exploit aspects of cognition or emotion to bias their hosts to spread them. Natural selection favors memes that are good at reproducing, which suggests that in time there will exist many memes that are very efficient replicators. Their accuracy is irrelevant for their survival, only their ability to replicate and find new hosts; memes that interest people and encourage them to spread the meme will thrive at the expense of less attractive versions.
- In memetics, ideas are viewed as almost independent creatures in a symbiotic relationship with human minds and cultures.
- Memes do not only influence behavior to promote replication, but many of the most successful memes have other side-effects (for example, being able to invoke various emotions) or promote their replication by being useful or through other features (like parasiting on other memes, e.g. parodies and imitations); using a biological analogy one could say symbiotic memes spread mainly using their usefulness, while parasitic memes compel the host to spread them. This compulsion can be more or less subtle, ranging from explicit orders like in chain letters ("Send ten copies of this letter to your friends") to implicit influences that link with our attitudes like the "Save the whales" meme.

- Host: A host must be able to possess at least *the potential capacity* to elaborate on the meme and to perform those cognitive tasks connected to the meme that we normally refer to as "understanding". This means that only humans can be hosts (animals can perhaps become hosts for simpler memes, but we will not discuss this here), at least until the development of artificial intelligences reaches further.
- Vector: A vector is anything that transports the meme between hosts without the capacity to reflect on the meme. Examples are a wall, a voice, an email-program, or a picture. Can a human be a vector? Yes she can, if she lacks the cognitive capacity (or interest) to elaborate on a specific meme. Then she is just a non-reflective carrier of the meme, much the same as a book. Note though that the human vector is still a potential host - or *inactive* host (Grant, 1990) - for the meme, should she suddenly choose to analyze the meme (in its widest sense) or achieve the contextual understanding which would make this possible.
- Dawkins (1976) suggests three qualities of a meme that gives it a high survival value: longevity, fecundity and copying fidelity.
- Religions represent some of the most powerful and elaborate meme complexes in existence today; they have evolved over millennia into countless variants and co- evolved with cultures.
- Religions are often better than other meme complexes (such as science) at explaining how the world works on an emotional level. They provide answers to existential questions that are emotionally appealing, creating a satisfying world model (which then becomes intellectually satisfying regardless of its consistency due to cognitive dissonance). Because religions seldom try to empirically prove themselves they cannot be disproved, which further aids their stability. A religion can spread regardless of the truth or falsity of its claims.
- It is our intention that by now you, by reading this text, have been infected with one of the strongest memes on the planet: The Meta-Meme, e.g. the meme about the theory of memes. It is our sincere hope that you will tell your friends about this (yes, transmission and further infection) or maybe even let them read this paper.

MEMES, MINDS, AND SELVES, By Susan Blackmore

- Memetic transmission is in some sense Lamarckian... Whether we see the process as Lamarckian also depends in part on what we consider the equivalent of the phenotype to be. If we follow some authors in persisting in seeing the organism as the phenotype then obviously the process is Lamarckian. If we follow Dawkins in treating meme products such as words, music, gestures, skills and fashions, as the equivalent of the phenotype, then the process still appears Lamarckian because these are the very things that are copied. However, we might follow his other suggestion that memes are still drifting clumsily about in their primeval soup. We can see the brain as the replicating machinery

for behaviors which have not yet created clear phenotypes. In this case the process is not so obviously Lamarckian.

- For many purposes we may proceed with a memetic analysis without specifying the size of the unit.
- Altruism may turn out to be yet another of the meme tricks that religions (those most powerful of meme-complexes) have purloined. Almost all of them thrive on making their members believe they are doing good.

WAKING FROM THE MEME DREAM, By Susan Blackmore

- Religions are special because they use just about every meme-trick in the book (which is presumably why they last so long and infect so many brains). Think of it this way. The idea of hell is initially useful because the fear of hell reinforces socially desirable behavior. Now add the idea that unbelievers go to hell, and the meme and any companions are well protected. The idea of God is a natural companion meme, assuaging fear and providing (spurious) comfort. The spread of the meme-complex is aided by exhortations to convert others and by tricks such as the celibate priesthood. Celibacy is a disaster for genes, but will help spread memes since a celibate priest has more time to spend promoting his faith.
- Another trick is to value faith and suppress the doubt that leads every child to ask difficult questions like “where is hell?” and “If God is so good, why did those people get tortured?” Note that science (and some forms of Buddhism) does the opposite and encourages doubt.
- Finally, once you’ve been infected with these meme-complexes they are hard to get rid of. If you try to throw them out, some even protect themselves with last-ditch threats of death, ex-communication, or burning in hell-fire for eternity.
- The point I want to make is that these religious memes have not survived for centuries because they are true, because they are useful to the genes, or because they make us happy. In fact I think they are false and are responsible for the worst miseries in human history. No - they have survived because they are selfish memes and are good at surviving - they need no other reason.
- Once you start to think this way a truly frightening prospect opens up. We have all become used to thinking of our bodies as biological organisms created by evolution. Yet we still like to think of ourselves as something more. We are in charge of our bodies, we run the show, we decide which ideas to believe in and which to reject. But do we really? If you begin to think about selfish memes it becomes clear that our ideas are in our heads because they are successful memes. American philosopher Dan Dennett (1995) concludes that a “person” is a particular sort of animal infested with memes. In other words you and I and all our friends are the products of two blind replicators, the genes and the memes.

- Like religions, astrology is a successful meme-complex. The idea that Leos get on well with Aquarians is unlikely to survive on its own, but as part of astrology is easy to remember and pass on. Astrology has obvious appeal that gets it into your brain in the first place; it provides a nice (though spurious) explanation for human differences and a comforting (though false) sense of predictability. It is easily expandable (you can go on adding new ideas forever!) and is highly resistant to being overturned by evidence. In fact the results of hundreds of experiments show that the claims of astrology are false but this has apparently not reduced belief in astrology one bit (Dean, Mather and Kelly, 1996). Clearly, once you believe in astrology it is hard work to root out all the beliefs and find alternatives. It may not be worth the effort. Thus we all become unwitting hosts to an enormous baggage of useless and even harmful meme-complexes.
- There are two systems I know of that are capable of dismantling meme-complexes (though I am sure there are others). Of course these systems are memes themselves but they are, if you like, meme-disinfectants, meme-eating memes, or “meme-complex destroying meme-complexes”. These two are science and Zen. ... Science works this way because of its ideals of truth and seeking evidence. It doesn't always live up to these ideals, but in principle it is capable of destroying any untruthful meme-complex by putting it to the test, by demanding evidence, or by devising an experiment. ... Zen does this too, though the methods are completely different. In Zen training every concept is held up to scrutiny, nothing is left uninvestigated, even the self who is doing the investigation is to be held up to the light and questioned. “Who are you?”

IMITATION AND THE DEFINITION OF A MEME, By Susan Blackmore

- There are many ways of defining the meme but there are two that we should perhaps take particularly seriously. First, Dawkins, who coined the term meme, described memes as units of cultural transmission which "*propagate themselves in the meme pool by ... a process which, in the broad sense, can be called imitation*" (Dawkins, 1976 p 192). Second, the Oxford English Dictionary defines a meme as follows: "*meme (mi:m), n. Biol. (shortened from mimeme ... that which is imitated, after GENE n.). An element of a culture that may be considered to be passed on by non-genetic means, esp. imitation*". Both these definitions include the critical point that memes are cultural information that is copied, and that it is copied by imitation. The OED is arguably the most important dictionary of the English language and is, as far as I know, the first to include the word 'meme'. It would be unfortunate if memeticists began to use definitions of the meme that were incompatible with the dictionary definition, unless there were good reasons for doing so.
- I have no doubt that in the future memetics will become involved in discovering just what the cognitive processes are that are involved in teaching, learning, instruction, and any other kinds of cultural transmission, but for the moment I suggest that we may consider all of them as in some way being forms of imitation, or based on the ability to imitate.

- My argument has been that the definition of the meme depends on, and should depend on, the concept of imitation. Therefore, only those things that can be passed on by imitation should count as memes. ... This means we can immediately exclude many things that a few authors have confusingly included as memes, such as perceptions, emotional states, cognitive maps, experiences in general, or "*anything that can be the subject of an instant of experience*". Furthermore we can build on the long history of research in animal behavior to distinguish imitation from contagion, and from individual and social learning, and so to eliminate from memetics the catching of yawns or all the many things we each learn for ourselves, by ourselves.

THE FORGET-MEME-NOT THEORY, By Susan Blackmore

- **What the Experts Say about Memetics**
 - "I think memes provide a neat way of explaining some of the paradoxes of cultural transmission and, if they help with explaining something that important, there had better be a science of them." Nicholas Humphrey, senior research fellow, London School of Economics
 - "The idea of memes is a meaningless metaphor". Stephen Jay Gould, professor of zoology, Harvard University
 - "A surprising number of people these days even talk about 'memes' ... Absurd as it may seem to imagine the seamless web of culture being disaggregated and transmitted between minds by gene-like replication, even some sociologists and philosophers have become captivated by the metaphor." Steven Rose, biologist, Open University
 - "It is an empty and misleading metaphor to call religion, science, or any other human activity a 'virus' or 'parasite'". Memes are a "useless and essentially superstitious notion." Mary Midgley, philosopher, Newcastle.
 - "Memetics needs to come up with supported, unique predictions and/or an existence proof to become valuable. The challenge to our speakers is to provide some support--- either theoretical or empirical---for the meme hypothesis." Robert Aunger, anthropologist, Cambridge.

EDITORIAL: MEMES MATTER, By P. Bouissac

- Although the *meme* hypothesis has been around for quite some time - it was first proposed by Richard Dawkins in 1976 - it does not seem to have had any decisive impact yet on the speculations and investigations of semioticians.

- As has been often the case in the history of scientific knowledge, an idea may inconsequentially float around for some time until it connects with other concepts or methods, usually apparently unrelated, to eventually precipitate, so to speak, and drastically change the way in which humans perceive their environment and themselves. Is the *meme* hypothesis of such a kind?
- Memes can become extinct for the same reasons as parasites. An examination of the life conditions of parasites thus sheds some heuristic light on memes' modalities of existence.
- Another important factor to be considered is that memes cannot be confused with evolved, wired-in, adaptive behavior. As any parasitic organisms, their biological dynamic exclusively concerns their own replication - in this respect they are strictly "selfish" to use the metaphor that Dawkins applied to genes - and consequently are neither detrimental nor beneficial to their hosts by necessity.
- As any organism, memes cannot be conceptualized independently of their environment. Adaptation by selection upon both genetic and memetic variations operates with respect to environmental factors. Catastrophic changes in memes' environment, that is the brain or a particular anatomical, physiological or chemical component of it, may eradicate a meme population, or trap it in a dead end without possibilities of further replications.

INTRODUCTION TO THE CRISIS OF THE MIND, By Richard Brodie

- This is the most surprising and most profound insight from the science of memetics: your thoughts are not always your own original ideas. You catch thoughts—you get infected with them, both directly from other people and indirectly from viruses of the mind. People don't seem to like the idea that they aren't in control of their thoughts. The reluctance of people to even consider this notion is probably the main reason the scientific work done so far is not better known. As we'll see, ideas people don't like have a hard time catching on.
- Once created, a virus of the mind gains a life *independent* of its creator and evolves quickly to infect as many people as possible.

TOWARDS A COGNITIVE MEMETICS: SOCIO-COGNITIVE MECHANISMS FOR MEMES SELECTION AND SPREADING, By Cristiano Castelfranchi

- The individual mind with its cognitive processes is the fundamental selection environment for memes. For the great majority of memes, it holds that: *if memes do not win within the mind of the individual, they cannot spread around in the population.*
- To be believed, something should be 'plausible'. Often we resist or reject a new item just because it is not 'plausible'. What is the basis of this kind of evaluation? Why is it a basis for rejection? ... Plausibility is *the credibility value assigned to the coming item from*

inside. It is evaluated just on the basis of previous knowledge: the same knowledge it has to be integrated with.

CHAPTER 11 FROM “THE SELFISH GENE”, By Richard Dawkins

- Examples of memes are tunes, ideas, catch-phrases, clothes fashions, ways of making pots or of building arches. Just as genes propagate themselves in the gene pool by leaping from body to body via sperms or eggs, so memes propagate themselves in the meme pool by leaping from brain to brain via a process which, in the broad sense, can be called imitation. If a scientist hears, or reads about, a good idea, he passed it on to his colleagues and students. He mentions it in his articles and his lectures. If the idea catches on, it can be said to propagate itself, spreading from brain to brain. ... Memes should be regarded as living structures, not just metaphorically but technically. When you plant a fertile meme in my mind you literally parasitize my brain, turning it into a vehicle for the meme's propagation in just the way that a virus may parasitize the genetic mechanism of a host cell.
- Cultural transmission is analogous to genetic transmission in that, although basically conservative, it can give rise to a form of evolution.
- I have been a bit negative about memes, but they have their cheerful side as well. When we die there are two things we can leave behind us: genes and memes. We were built as gene machines, created to pass on our genes. But that aspect of us will be forgotten in three generations. Your child, even your grandchild, may bear a resemblance to you, perhaps in facial features, in a talent for music, in the color of her hair. But as each generation passes, the contribution of your genes is halved. It does not take long to reach negligible proportions. Our genes may be immortal but the *collection* of genes that is any one of us is bound to crumble away. ... But if you contribute to the world's culture, if you have a good idea, compose a tune, invent a sparking plug, write a poem, it may live on, intact, long after your genes have dissolved in the common pool. Socrates may or may not have a gene or two alive in the world today ... but who cares? The meme-complexes of Socrates, Leonardo, Copernicus and Marconi are still going strong.
- Faith cannot move mountains (though generations of children are solemnly told the contrary and believe it). But it is capable of driving people to such dangerous folly that faith seems to me to qualify as a kind of mental illness. It leads people to believe in whatever it is so strongly that in extreme cases they are prepared to kill and die for it without the need for further justification. Keith Henson has coined the name 'memeoids' for 'victims that have been taken over by a meme to the extent that their own survival becomes inconsequential ... You see lots of these people on the evening news ... Faith is powerful enough to immunize people against all appeals to pity, to forgiveness, to decent human feelings. It even immunizes them against fear, if they honestly believe that a martyr's death will send them straight to heaven. What a weapon! Religious faith deserves a chapter to itself in the annals of war technology, on an even footing with the longbow, the warhorse, the tank, and the hydrogen bomb.

SURVIVAL OF THE INSTITUTIONALLY FITTEST CONCEPTS, By Martin de Jong

- Memetics, on the other hand, being a theoretically rich and promising framework badly needs empirical filling.

USING MEMETICS TO GROW MEMETICS, By David K. Dirlam

- From an empiricist's point of view, empirical research in memetics is currently difficult to reproduce. No one has yet written the methodological recipe book for memetics research.

MEMES AND THE EXPLOITATION OF IMAGINATION, By Daniel Dennett

- Evolution occurs whenever the following conditions exist:
 - Variation: a continuing abundance of different elements
 - Heredity or replication: the elements have the capacity to create copies or replicas of themselves
 - Differential "fitness": the number of copies of an element that are created in a given time varies, depending on interactions between the features of that element (whatever it is that makes it different from other elements) and features of the environment in which it persists.
- This is a new way of thinking about ideas. It is also, I hope to show, a good way, but at the outset the perspective it provides is distinctly unsettling, even appalling. We can sum it up with a slogan: A scholar is just a library's way of making another library.
- I don't know about you, but I am not initially attracted by the idea of my brain as a sort of dung heap in which the larvae of other people's ideas renew themselves, before sending out copies of themselves in an informational Diaspora. It does seem to rob my mind of its importance as both author and critic. Who is in charge, according to this vision--we or our memes?
- The first rule of memes, as it is for genes, is that replication is not necessarily for the good of anything; replicators flourish that are good at ... replicating! -- for whatever reason.
- A meme that made its bodies run over cliffs would have a fate like that of a gene for making bodies run over cliffs. It would tend to be eliminated from the meme-pool. . . . But this does not mean that the ultimate criterion for success in meme selection is gene survival. . . . Obviously a meme that causes individuals bearing it to kill themselves has a grave disadvantage, but not necessarily a fatal one. . . . A suicidal meme can spread, as

when a dramatic and well-publicized martyrdom inspires others to die for a deeply loved cause, and this in turn inspires others to die, and so on.

- The important point is that there is no *necessary* connection between a meme's replicative power, its "fitness" from *its* point of view, and its contribution to *our* fitness (by whatever standard we judge that). The situation is not totally desperate. While some memes definitely manipulate us into collaborating on their replication *in spite of* our judging them useless or ugly or even dangerous to our health and welfare, many--most, if we are lucky--of the memes that replicate themselves do so not just *with* our blessings, but *because of* our esteem for them. I think there can be little controversy that the following memes are, all things considered, good *from our perspective*, and not just from their own perspective as selfish self-replicators.
- Memes now spread around the world at the speed of light, and replicate at rates that make even fruit flies and yeast cells look glacial in comparison. They leap promiscuously from vehicle to vehicle, and from medium to medium, and are proving to be virtually unquarantinable. Memes, like genes, are *potentially* immortal, but, like genes, they depend on the existence of a continuous chain of physical vehicles, persisting in the face of the Second Law of Thermodynamics. Books are relatively permanent, and inscriptions on monuments even more permanent, but unless these are under the protection of human conservators, they tend to dissolve in time. As with genes, immortality is more a matter of replication than of the longevity of individual vehicles. The preservation of the Platonic memes, via a series of copies of copies, is a particularly striking case of this. Although some papyrus fragments of Plato's texts roughly contemporaneous with him have been recently discovered, the survival of the memes owes almost nothing to such long-range persistence. Today's libraries contain thousands if not millions of physical copies (and translations) of the *Meno*, and the key ancestors in the transmission of this text turned to dust centuries ago.
- Minds are in limited supply, and each mind has a limited capacity for memes, and hence there is a considerable competition among memes for entry into as many minds as possible. This competition is the major selective force in the infosphere, and, just as in the biosphere, the challenge has been met with great ingenuity. For instance, whatever virtues (from our perspective) the following memes have, they have in common the property of having phenotypic expressions that tend to make their own replication more likely by disabling or pre-empting the environmental forces that would tend to extinguish them: the meme for *faith*, which discourages the exercise of the sort of critical judgment that might decide that the idea of faith was all things considered a dangerous idea; the meme for *tolerance* or *free speech*, the meme of including in a chain letter a warning about the terrible fates of those who have broken the chain in the past, the *conspiracy theory* meme, which has a built-in response to the objection that there is no good evidence of the conspiracy: "Of course not--that's how powerful the conspiracy is!" Some of these memes are "good" perhaps and others "bad"; what they have in common is a phenotypic effect that systematically tends to disable the selective forces arrayed against them. Other things being equal, population memetics predicts that conspiracy theory memes will persist quite independently of their truth, and the meme for faith is apt to

secure its own survival, and that of the religious memes that ride piggyback on it, in even the most rationalistic environments. Indeed, the meme for faith exhibits *frequency-dependent fitness*: it flourishes particularly in the company of rationalistic memes.

- *Homo sapiens* have been around for half a million years. The first serious invasion of memes began with spoken language only tens of thousands of years ago, and the second great wave, riding on the meme for writing, is considerably less than ten thousand years in progress--a brief moment in biological time. Since memetic evolution occurs on a time scale thousands of times faster than genetic evolution, however, in the period since there have been memes--only tens of thousands of years--the contributing effects of meme-structures on our constitution--on human phenotypes--vastly outweigh the effects of genetic evolution during that period.

MEMES: MYTHS, MISUNDERSTANDINGS, AND MISGIVINGS, By Daniel C. Dennett

- Some memes are like domesticated animals; they are prized for their benefits, and their replication is closely fostered and relatively well understood by their human owners. Some memes are more like rats; they thrive in the human environment in spite of being positively selected against--ineffectually--by their unwilling hosts. And some are more like bacteria or other viruses, commandeering aspects of human behavior (provoking sneezing, for instance) in their "efforts" to propagate from host to host. There is artificial selection of "good" memes--like the memes of arithmetic and writing, which are carefully taught to each new generation. And there is unconscious selection of memes of all sorts--like the subtle mutations in pronunciation that spread through linguistic groups, presumably with some efficiency advantage, but perhaps just hitchhiking on some quirk of human preference. And there is unconscious selection of memes that are positively a menace, but which prey on flaws in the human decision-making apparatus, as provided for in the genome and enhanced and adjusted by other cultural innovations--such as the abducted-by-aliens meme, which makes perfect sense when its own fitness as a cultural replicator is considered. Only the meme's-eye perspective unites all these possibilities under one view.

THE REVEALED POVERTY OF THE GENE-MEME ANALOGY: WHY MEMETICS PER SE HAS FAILED TO PRODUCE SUBSTANTIVE RESULTS, By Bruce Edmonds

- Here I distinguish between what might be called the "broad" and the "narrow" approaches to memetics. The former, broad, approach involves modeling communication or other social phenomena using approaches which are evolutionary in structure. Work within this approach is often done without appealing to "memes" or "memetics" since it can be easily accommodated within other frameworks. In other words, it does not require an analogy with genetics. The later, narrow, sense involves a closer analogy between genes and memes – not necessarily 100% direct, but sufficiently direct so as to justify the

epithet of "memetics". What has failed is the narrow approach – that of memetics. Work continues within the broad approach, albeit under other names, and in other journals.

- I claim that the underlying reason memetics has failed is that it has not provided any extra explanatory or predictive power beyond that available without the gene-meme analogy. Thus whilst the idea of memes has retained its attractiveness for some in terms of a framework for thinking about phenomena, it has not provided any "added value" in terms of providing new understanding of phenomena. ... The ability to think of some phenomena in a particular way (or describe it using a certain framework), does not mean that the phenomena has those properties in any significant sense.
- Academics who seek to study memetics in serious ways have suffered in the respect that they are often confused with those on the penumbra for whom memetics is a fad. However, this mistake is grounded in an element of truth. The study of memetics has been characterized by theoretical discussion of extreme abstraction and over ambition. Thus for example, before any evidence is available or detailed causal models constructed, attempts have been made to "explain" some immensely complex phenomena such as religion in general or consciousness. This sort of discussion shifts any study of memetics from the realm of science to that of a philosophy...

A JUSTIFICATION OF SOCIETAL ALTRUISM ACCORDING TO THE MEMETIC APPLICATION OF HAMILTON'S RULE, By John R. Evers

- The essentials of kin selection and inclusive fitness are summarized according to a simple equation, called "Hamilton's Rule," which is expressed: $C/B < b$. "This says that the cost C (which is the loss in expected personal reproductive success through the self-sacrificing behavior) divided by the benefit B (the increase in the relatives' expected reproductive success) must be less than b , the probability that the relatives have the same allele," if the altruist gene is to survive natural selection.
- Any meme can be defined generally as a *rule of behavior*, encoded by functional neuronal groups or pathways. Behavior is action, whether mental or physical. Ideas such as *tying shoe-laces* or *opening a door* represent rules of physical action, i.e., rules of patterned neural-muscular interaction. Concepts such as *apple*, *seven*, or *causality*, represent rules of mental action, or rules of cognition, i.e., rules of patterned neural-neural interaction. Hence, physical movement is governed by memes which represent rules of physical action and thought is governed by memes which represent rules of mental action. ... If memes are units of natural selection (allowing for a memetic application of Hamilton's Rule); and, if memes copy horizontally (allowing the "memetic family" to extend beyond the scope of the genetic family); and, if memes can be directly responsible for altruistic behavior, then memetically driven and inclusively fit altruism can extend to the whole of any given (freely communicating) human population according to the mathematical purity of Hamilton's Rule.

- Hamilton's Rule offers a comprehensive justification for general (intra-societal or intra-cultural) altruism. Meanwhile, it can be said with newfound certainty that purely altruistic behavior is *possible* within any memetically fertile population.

STROLLING THROUGH THE MEMETIC MINE FIELD, By Leon Felkins

- It is obvious, however, that many memes are "planted" in the group by certain individuals for their own reasons. The politicians, the schools, the press, the clergy and others are guilty of sowing a constant stream of memes within the populace and encouraging their growth.
- Can we think without being influenced by memes and genes? While we can't completely eliminate the influence of memes and genes we certainly can diminish their impact. Further, we can adopt the "Scientific Method" which requires that all conclusions be subject to verification. That is, we can keep an open mind for errors in our thinking and try to minimize accepting anything on blind faith.
- Funerals and other ceremonies surrounding a death are powerful and ancient memes that remain unchallenged in the most modern of communities. The United States has spent millions retrieving the bones of service men and others from foreign countries without a thought as to what could be in those bones that make them so valuable.
- Religion has had a great deal of success with memes. In fact, for anyone wanting to do research on the impact of memes, this is probably your best laboratory.

VIRAL MARKETING: SPREAD A COLD, CATCH A CUSTOMER, By Frank Fiore

- They call it "viral marketing." Having someone else spread the word to drive more visitors to your site. ... Let's face it. The best kind of marketing is the kind you don't have to do yourself. Especially if you're a small business on the web with a limited advertising budget. Viral marketing is like it sounds. Call it word-of-mouth, spawning, self-propagation -- organic. ... Great new idea, right? Nope. Viral marketing has been around forever. Spreading the word through word-of-mouth was the world's first form of marketing. But the Internet has taken this organic form of marketing to new heights by making communications better and communities of people tighter -- thus making word-of-mouth even more effective.

MEME AND VARIATIONS: A COMPUTATIONAL MODEL OF CULTURAL EVOLUTION, By Liane M. Gabora

- In order for a pattern of information to evolve, we need a way of generating variations of the pattern, and a way of selectively replicating it.

- Ideas, like genomes, are patterns that evolve; however their evolution is not subject to the same constraints, and employs different mechanisms. The generation of variation is less random in cultural evolution than in biological evolution; it reflects the accumulated knowledge of individuals, and the social structure in which they are embedded. In cultural evolution, selective replication is Lamarckian; an idea can be modified through experience after it has been phenotypically expressed. Genetic information is coded in a physical sequence of nucleotides, and contains the instructions for its own replication, whereas ideas are coded in patterns of neuron activation, and do not contain the instructions for their replication; they rely on human hosts to replicate them. Ideas that satisfy our needs or drives are preferentially learned and implemented.

A DAY IN THE LIFE OF A MEME, By Liane Gabora

- Some believe that looking to biological evolution to gain insight into cultural evolution is a waste of time. As Gould put it: "Biological evolution is a bad analog for cultural change... biological evolution is powered by natural selection, cultural evolution by a different set of principles that I understand but dimly."
- Skeptics may wonder how we can develop a theory of cultural evolution before we understand how memes are instantiated in the brain. This situation has a precedent: Darwin came up with the theory of biological evolution through natural selection before the discovery of genes.
- The world can be viewed as a vast network of computations wherein information is created, transformed, and destroyed. This information often exhibits pattern, or statistical regularity that can be expressed mathematically.
- Today the Earth is embedded with artifacts like computer networks and circuses that cannot be accounted for by appeal to either the properties of matter or biological evolution. That is, biological evolution does not provide us with adequate explanatory power to account for the existence of computers any more than the properties of matter can explain the existence of giraffes. Computers are manifestations of yet another causal principle: the evolution of culture.
- Which memes spread and which ones die off reflects the dynamics of the entire society of individuals hosting them.
- Durham defines a meme as "any kind, amount, and configuration of information in culture that shows both variation and coherent transmission." Problems with this definition arise because it does not distinguish between cultural information as mental representation and cultural information as implemented behavior or artifact.
- What constitutes a meme ... will differ amongst individuals and within an individual over time.

- The Hamming distance between two memes is the number of bits that differ. (So the Hamming distance between 11111 and 11100 is two.) Since each meme has an antipode (for example, the antipode of 11111 is 00000), the space of all possible memes can be visualized as a sphere. The address of a meme is the information pattern that specifies where the meme is stored. ... The smaller the Hamming distance between two memes, the higher the probability that they will be retrieved simultaneously and blended together in the focus
- If L is the number of possible features in a meme, the number of possible memes is 2^L . Assuming L is large the size this space is enormous, so the memory is sparse in that it stores only a small fraction of the set of all possible memes.
- Recall that to implement a meme is to express it, so that it crystallizes from the world of ideas into words or body language or objects in the physical world. Memes fool potential hosts into wanting or identifying with them, by aligning themselves with memes we already hold dear (as advertisers are well aware). The more we value ourselves in terms of the memes and implemented artifacts we possess or lack, the more vulnerable we are to ever-more-seductive forms of persuasion and advertising which tie up time, energy, and resources that could be applied toward other goals.
- One way to defend oneself against painful or manipulative memes is to construct ... a meme-immunological system; that is, formulate new memes specifically to deflect memetic antigens. However constructing memetic antibodies of this sort is time-consuming, and like any immunological response it has to be repeated every time the outside agent evolves a counter-response.
- Although the cultural evolution of memes operates through very different mechanisms from those of biology, culture is the only system comparable to biology, because it is the only other system to exhibit the imperative features of evolution adaptive exploration and transformation of an information space through variation, selection, and transmission. All patterns in the information we encounter can be traced to either (1) the physical constraints and self-organizing properties of matter, (2) biological evolution, (3) cultural evolution, or (4) interactions between these causal principles. ... One important difference between the two forms of evolution is that culture is less random--new patterns have a greater-than-chance probability of being more fit than their predecessors.

MEMES: THE CREATIVE SPARK, By Liane M. Gabora

- Memes, as advertisers are well aware, can fool potential hosts into believing they are needed by associating with memes we already identify as necessary.

WHY THE “THOUGHT CONTAGION” METAPHOR IS RETARDING PROGRESS OF MEMETICS, By Derek Gatherer

- Broadly, my intention is to show that what is probably the most popular, even one might say the 'orthodox', definition of the meme as a 'unit of information residing in a brain' ... presents us with serious philosophical difficulties that may hamper (and indeed are already hampering) the development of memetics as a science. I shall argue that an earlier and broader picture of the meme as a 'unit of cultural transmission, or a unit of imitation' ... is in many respects a better working definition, despite the fact that it is now generally regarded as obsolete.
- I shall focus on two main theses: (1) There can be no population memetics; (2) Memetics cannot be used to study why beliefs spread. In brief, thesis 1 is consequent on the impossibility of quantifying meme frequencies in populations, since this requires a clear meme-host relationship and that is precisely what we cannot obtain in most cases ... Thesis 2 is consequent on the impossibility of accurately identifying when belief has been replicated or transmitted. It is possible to accept thesis 2 while still rejecting thesis 1. However, if thesis 1 is accepted, thesis 2 is a necessary consequence.
- The central flaw in the 'thought contagion' and mind virus' hypotheses may be summed up in a single phrase: these theories require individuals to *have* memes. ... The state of having a meme is taken as synonymous with the state of having a certain informational pattern in the brain.
- Gene frequencies are of course abstractions, pure quantitative values, but they are abstractions which relate directly to a physical reality, i.e., the reality of gene sequences within the bodies of individuals. Thus, providing the required technical methods are available, one may derive an unambiguous estimation of gene frequencies which are comparable between one population and another. ... Memes, on the other hand, are more difficult to pin down. [In one definition] Dawkins included concepts, cultural artifacts and subjective states such as beliefs, whereas [in another definition] Dawkins restricted memes to units of neural information giving rise to behaviours or the production of artifacts ... Dawkins is careful to stipulate that when a meme is transmitted from one brain to another, it is not necessary that exact neural configurations are reproduced. Two individuals, who are exhibiting the same mental state, entertaining the same idea, performing the same behaviour, are taken to have the same meme, for all intents and purposes - even if their neural configurations are not identical. Thus at this most basic physical level, [in Dawkins latter definition] memes are less tangible than genes. They are merely informational specifications within brains.
- Even if one were able to use some method of scanning an individual's brain to discover the internal neural configuration, we would not be able to identify the Dawkins memes [as units of information] of that individual.
- While we *can* often observe the communication of information, we can *never* directly observe transmission of belief. *Information and belief are not the same kind of thing.*

- Nevertheless, behavior, and the artifacts produced by behavior, such as micropipettes, laboratories and cathedrals, *is* more easily quantified than conceptual abstractions. It is possible to measure the increase in the number of Christian churches per capita in the Roman Empire, to measure the number of scientific articles on the subject of Darwinism per total articles published, to measure the percentage of Aka hunters carrying crossbows, to measure the percentage of votes cast for political parties defining themselves as socialist etc. *These* are our meme frequency statistics, or as near as we shall ever get to such a thing. *These* memes are behaviours, or artefacts that are the products of behaviour, and *not* abstract informational instantiations in individual brains. ... And, crucially, individuals do not *have* any of these memes. They build them, say them, do them, make them, assent to them or deny them, but the memes are entirely outside the human beings that generate them. These meme frequency statistics are *not* per capita of human populations, and therefore *do not constitute a body of data which is formally analogous to that of population genetics*. For this reason, there can be no population memetics.
- One who spends so much effort criticizing the meme definitions of others, ought to present a clear target for his own critics. The following is therefore offered: **Meme**: *an observable cultural phenomenon, such as a behaviour, artifact or an objective piece of information, which is copied, imitated or learned, and thus may replicate within a cultural system. Objective information includes instructions, norms, rules, institutions and social practices provided they are observable.*

THE CASE FOR COMMENTARY, By Derek Gatherer

- The article 'Why the Thought Contagion Metaphor is Retarding the Progress of Memetics' argues that the field of memetics took a wrong turning in the early 1980s, with the result that all subsequent memetic theorizing has driven down the same blind alley. The wrong turning was to substitute the earlier, flexible definition of a meme (which in the article I term **Dawkins A**) with a far narrower and more specific definition as a unit of information in a mind or brain (termed **Dawkins B**). ... Since science generally abhors vagueness and thrives on precise definitions, such a move naturally seemed like a step forward. In this case, however, it was counter-productive, since:
 - Direct observation was relegated to a subsidiary role, while inference and speculation took centre stage. The derivation of internal memes from behavior relies on acts of the most naive inference. This is not the same situation as that of a classical geneticist of the early 20th century, since genes were not naively inferred from phenotypes, but were indirectly demonstrable as segregation ratios, patterns of independent assortment or linkage. There is no equivalent phenomenology in memetics. Internal memes are not even indirectly demonstrable. Their existence cannot be independently verified in any way.
 - Quantification became impossible. We cannot quantify any internal mental unit, and quantification is as essential as precise definitions (if not more so). While it is possible to quantify behavior, either roughly in the field or more precisely in the

laboratory, such quantification of behaviour does not translate into quantification of internal memes, unless the internal meme and the behaviour exist in a one-to-one correspondence. There is no evidence for this.

- The theory lacks explanatory power. To say that behavior can be explained in terms of something which cannot be observed is unhelpful. In any case, there is also no evidence that replication of behaviour is necessarily correlated with replication of internal mental states. We have no grounds for believing that thoughts are contagious, and such a view trivializes psychology.
 - Lynch's calculus of mnemon conjugations is incompatible with any present thinking in either cognitive sciences or linguistics. The picture of the mind as a stack of `awareness of statement x' and `belief in statement x' would require the mind to store language in a manner reminiscent of a computer RAM. Such possibilities were effectively excluded by Chomsky in the early 1950s.
- I should therefore like to ask the commentators if they consider `internal' memetics to be still tenable in the light of these criticisms. If so, how do they believe it should be constituted as an experimental science (as opposed to a pseudoscience dealing in postulated unobservable entities, where neither verification nor falsification are possible)? If the commentators agree with me that `internal' memetics is untenable, do they tend towards my quasi-behaviorist version of `external' memetics, or have they a third alternative?

A PLEA FOR METHODOLOGICAL DARWINISM: a COMMENTARY ON ROSE'S PAPER – CONTROVERSIES IN MEME THEORY, by Derek Gatherer

- Dennett ... takes the meme theory a stage further. Now the meme is not seen merely as a replicator within consciousness, but as the essence of consciousness itself. ... The illusion of consciousness is produced through the combined action of myriads of behavioral and abstract memes.

MEMETICS: A SYSTEMS METABIOLGY (Version 950220), By Ron Hale-Evans

Intrinsic factors in memetic reproduction: "hooks":

1. Intrinsically rewarding factors
 - 1.1. Promises of reward
 - 1.2. Interestingness of meme
 - 1.2.1. Promises of reward
 - 1.2.2. Aesthetic qualities
 - 1.2.3. Humor
 - 1.2.4. Strangeness/novelty
 - 1.3. Feelings of superiority

- 1.4. Scapegoating
- 1.5. Explanation of everything
- 1.6. Usefulness
- 1.7. Self-directed reward
 - 1.7.1. Unconditional reward
 - 1.7.2. For obeying
- 1.8. Other-directed conditional reward
- 2. Claiming intrinsically rewarding qualities
- 3. Intrinsically punishing factors
 - 3.1. Threats of punishment: fear
 - 3.2. Guilt
 - 3.3. Self-directed conditional physical harm
 - 3.4. Other-directed conditional harm
- 4. Mechanical factors in reproduction
 - 4.1. Ease of reproduction
 - 4.1.1. Simplicity
 - 4.1.2. Comprehensibility
 - 4.1.3. Reproductive ability of medium
 - 4.1.4. Copying fidelity
 - 4.1.4.1. Cohesiveness
 - 4.1.4.2. Noteworthiness
 - 4.2. Redundancy
 - 4.3. Longevity
 - 4.4. Plausibility
 - 4.5. Adaptability
 - 4.5.1. Syncretism
 - 4.5.1.1. Subsuming other memes
 - 4.5.1.2. Consistency with other memes: cooperation
 - 4.5.2. Intolerance to other memes
 - 4.6. Precise marketing
- 5. Claiming mechanical factors
- 6. General commands to host mind
 - 6.1. Faith
 - 6.2. Commands to explore the meme complex
 - 6.3. Commands to spread the meme
 - 6.4. Duty

Extrinsic factors in memetic reproduction:

- 7. Input transducer
 - 7.1. Isolation
 - 7.2. Events consistent with meme
- 8. Internal transducer
 - 8.1. Stresses in population increasing suggestibility
- 9. Channel and net
 - 9.1. Fitness of channel and net --

- 9.1.1. High information capacity
 - 9.1.2. Signal-to-noise ratio
 - 9.1.3. Ease of use
- 10. Decoder
 - 10.1. Availability of decoder units for population
 - 10.2. Ability of population to interpret memes
- 11. Associator
 - 11.1. Suggestibility of population
- 12. Memory
 - 12.1. Presence of consistent memes
 - 12.2. Durability of memory
 - 12.3. Ease of storage and recall
- 13. Decider
 - 13.1. Favor of central authority
- 14. Encoder
 - 14.1. Intelligence of those propagating the meme
- 15. Output transducer
 - 15.1. Attractiveness of those propagating the meme

AN OPEN MIND IS NOT AN EMPTY MIND: EXPERIMENTS IN THE META-NOOSPHERE, By David Hales

- This paper builds on previous work using the Minimeme model ... The model is extended to incorporate open-mindedness meta-memes (memes about memes). In the scenarios presented such meta-memes have dramatic effects, increasing the optimality of population distribution and the accuracy of existing beliefs. It is argued that artificial society experimentation offers a potentially fruitful response to the inherent problems of building new meme theory.

WHAT MAKES A MEME SUCCESSFUL? SELECTION CRITERIA FOR CULTURAL EVOLUTION, By Francis Heylighen

- To be replicated, a meme must pass successfully through four subsequent stages: 1) assimilation by an individual, who thereby becomes a *host* of the meme; 2) retention in that individual's memory; 3) expression by the individual in language, behavior or another form that can be perceived by others; 4) transmission of the thus created message or *meme vehicle* to one or more other individuals. This last stage is followed again by stage 1, thus closing the replication loop. At each stage there is selection, meaning that some memes will be eliminated.
- The overall survival rate of a meme m can be expressed as the meme *fitness* $F(m)$, which measures the average number of memes at moment t divided by the average number of memes at the previous time step or "generation" $t - 1$. This fitness can be expressed in a

simplified model as the product of the fitnesses or survival rates for each of the four stages, respectively assimilation A , retention R , expression E and transmission T :

- $F(m) = A(m) \cdot R(m) \cdot E(m) \cdot T(m)$
- A denotes the proportion of memes vehicles encountered (or memes independently discovered) by the host that are assimilated. R represents the proportion of these assimilated memes that are retained in memory. Therefore, $A \leq 1$, $R \leq 1$. E is the number of times a retained meme is expressed by the host. T is the number of copies of an expression that is transmitted to a potential new host. Unlike A and R , E and T do not have an upper bound, although E is likely to be more restricted than T . Note that F is zero as soon as one of its components (A , R , E , T) is zero. This expresses the fact that a meme must successfully pass through *all* four stages in order to replicate. Also note that for a meme to spread ($F > 1$), you must have $E > 1$ or $T > 1$.

MATHEMATICAL MODELS FOR MEMETICS, By Jeremy R. Kendal and Kevin N. Laland

- The science of memetics aims to understand the evolution of socially transmitted cultural traits. Recently attention has focused on the interaction between memetic and genetic evolution, a phenomenon described as meme-gene co-evolution.

DIFFERENT TYPES OF MEMES: RECIPEMES, SELECTEMES, AND EXPLANEMES, By John Z. Langrish

- This paper attempts to provide three directions for advancing Dawkins' original description of memes as 'units' of cultural transmission'. These three directions are
 - There could be different types of memes
 - Memes are not 'units'
 - The transmission of memes might not be restricted to something called 'culture'
- A biological perspective allows for different types of memes with different transmission mechanisms. The disease type mechanism (epidemiology) has been over emphasised and is only one such mechanism. Three types of memes are suggested and given the names recipemes, selectemes and explanemes.
- Much of what has been written about memes can be summed up by the title of Aaron Lynch's book (1996), 'Thought Contagion'. This approach has been used to attack both Communism and religion, provoking a counter attack by John Bowker whose 'Is God a Virus?' (1995) attempts to bring free will into the discussion. ... If some extra-galactic intelligence discovered our earth, they might be expected to be interested in carbon based life. However, if after twenty years they had only studied viruses and parasites we might

think they were deficient in curiosity or just weird. Why no interest in ants, elephants, spiders, trees, eagles, coral, sharks or fungi? It is a bit like that with memes; why such little interest in the memes of technology, poetry, design, economics and all those interesting human activities involving ideas. After all, Dawkins' original description of a meme included 'ways of making pots and building arches'.

UNITS, EVENTS, AND DYNAMICS IN MEMETIC EVOLUTION, By Aaron Lynch

- In *The Extended Phenotype* Dawkins more explicitly clarified that "a meme should be regarded as a unit of information residing in the brain". I have since taken this meaning of the word "meme" and refined it into a more technical definition suitable for symbolic and mathematical analysis.
- ... The further development of strong theoretical treatments, formal definitions of terms, mathematical analyses, discussions of empirical methodology, and criteria for falsifiability remain subjects of interest among hard core scientists.
- Defining the word meme concisely but technically without reference to the other neologisms, we have: MEME: A memory item, or portion of an organism's neurally-stored information, identified using the abstraction system of the observer, whose instantiation depended critically on causation by prior instantiation of the same memory item in one or more other organisms' nervous systems. ("Sameness" of memory items is determined with respect to the above-mentioned abstraction system of the observer.)
- Some efforts have been made to incorporate the idea of "size" into the definition of the word *meme*. This includes those who favor the "smallest" possible units, as well as those who favor the "largest" possible units. Unlike those who expand the definition of *meme*, these scientists are indeed looking for ways to render the meaning more specific. Yet not all attempts at specificity are equally useful in the study of real phenomena.
- The sort of predictions generated by mathematical models and computer simulations are falsifiable. This provides a general method for attempting to falsify specific memetic hypotheses. In general, propagation parameters can be measured over the duration of the time interval being modeled, as can the initial host populations of the memes under study. If the propagation parameters remain in some specified interval, then the final host population plus or minus a calculable error margin should be measured at the end of that interval. A host population measurement outside those error margins would then falsify the model being used for the specific memes under study. The procedure can be quite elaborate, as it involves conducting surveys and performing difficult computations.
- At present, there is no brain scanning device that tells unambiguously whether someone holds a particular belief or not. Nor is there a memory probe that recovers all the communications that lead someone to adopt a particular idea. This means that measuring host populations and propagation parameters must depend on survey methodology. Questionnaires and interview protocols may thus form functional definitions of the

abstractions used in memetics. ... The rates of occurrence of specific events must also be measured for use in a quantitative model, in order to determine the propagation parameters.

A RESPONSE TO PAUL MARSDEN OF A REVIEW OF *THOUGHT CONTAGION: HOW BELIEF SPREADS THROUGH SOCIETY*, By Aaron Lynch

- **MEME:** A memory item, or portion of an organism's neurally-stored information, whose occurrence depended critically on causation by prior occurrence of the same memory item in one or more other organisms' nervous systems.
 - This definition identifies the minimum conditions needed to achieve the recursive process (or algorithm) that forms the basis of evolution by natural selection in interpersonally transmitted brain-stored information. It becomes the basis of transmission event diagrams and differential equations ... useful in developing computer simulations of the meme transmission patterns ...

DAWKINS BAD IDEA: MEMES, GENES, AND THE METAPHORS OF PSYCHOLOGY, By Arthur J. Marr

- In times past, if the devil didn't get you, the vapors would, and if they didn't, humours, poisons, bile or any number of fanciful entities would do you in. With Pasteur and 19th century biology, these agents of illness were replaced with microscopic organisms, and the invention of the disease model made it easy to attribute your aches and pains to malicious bacteria, viruses, or other little microscopic buggers. Of course, then as now, few people understand the actual biological processes that are responsible for disease, but the *metaphors* for disease do just fine, and have been duly incorporated into the common vernacular. Some may say that these metaphors have worked a bit too well, since they have made a Procrustean stretch to cover all sorts of behaviors, from alcoholism to gambling.
- The definition of a meme as an independent conceptual object is ultimately not simple, but simplistic, since it does not denote the web of informative relationships between behavior and the environment that is denoted by consciously and nonconsciously by the mind and body proper. For example, the concept of the sport of football is a well traveled meme to be sure.
- Football represents a rather involved information pattern that has infected the minds of young men nationwide, and football games, commentary, and assorted chatter has parasitized not only the minds of people, but the network airwaves, the written media, and many unwilling housewives. But is a football game an indivisible meme like entity, or is it somewhat different than the sum of its parts? Actually, the 'meme' of football is not a singular information pattern that replicates like a strand of DNA, but rather emerges from a web of separate patterns of information that are mediated not only by consciously perceived information but by neural and somatic activating processes that we otherwise

call emotion. The meme of football is not just a compendium of rules, but comprises the memory of the somatic responses that occur while watching (excitement, depression), the natural feeling of elation that occurs with a high state of alertness, the virtual extension of control over all those partisans of the losing team, the constantly changing and stimulating prediction error that occurs as one play after another unfolds, the smell and taste of hot dogs and beer, the camaraderie of friends, and so on. The meme of football is in other words a web of perceptual relationships that is volatile and constantly changing.

OPERATIONALIZING MEMETICS: SUICIDE, THE WERTHER EFFECT, AND THE WORK OF DAVID PHILLIPS, By Paul Marsden

- One of the major challenges currently facing memetics is the issue of how to successfully *operationalise* the emerging paradigm. In other words, how can we exploit the innovative analytical framework of memetics in order to generate a body of theoretically informed empirical research? Whilst there are some important *theoretical* issues that have yet to be resolved, the future success of memetics, qua academic discipline, may depend not so much on elaborate theoretical developments, but on the results of *empirical* research findings. Operationalising memetics will not only involve subjecting memetic theory *itself* to empirical testing, but it will also mean assessing the usefulness of the paradigm in describing, understanding and explaining the sociocultural patterns and phenomena that are the *traditional foci of the social sciences*.
- "No fact is more readily transmissible by contagion than suicide." Emile Durkheim (Le Suicide [1897] 1951:141)
- Summary of empirical research on social contagions conducted by Phillips:

The Werther Effect: Fact or Fiction - Summary of Research by D.P. Phillips	
Key findings and Conclusion	Source
Suicide rates increased significantly after suicide stories were reported newspaper stories. The increase was proportional to the amount of newspaper coverage devoted to the suicide stories	American Sociological Review 1974 Vol. 39:340-54
Car accident fatalities increased following media representations of suicide implying that some car accident fatalities were in fact imitative suicides	Science 1977 196: 1464-65
Car accident fatalities, particularly those resulting from single-car accidents increased significantly three days after a suicide story was publicised in the newspaper press. The increase was proportional to the intensity of the publicity, and the age of the accident victim was positively correlated with the age of the suicide story victim. There was also a corresponding correlation between murder-suicide stories and multiple car crashes involving passenger deaths.	American Journal of Sociology 1979 Vol. 84 No.5: 1150 -1174
Publicised murder-suicides were followed by an increase in airplane crashes (airline and non-commercial). The increase in airplane crashes was proportional to the degree of coverage that these stories received	Social Forces 1980 Vol. 58 (Jun): 1001-1024
Daily US suicide rates increased significantly (for a period of less than ten days) following the appearance of highly publicised suicide stories on television	American Sociological Review

evening news programmes.	1982 Vol. 47: 802-809
Suicide rates, motor vehicle fatality statistics and non-fatal accidents all rose immediately following the transmission of fictional televised suicide stories in 1977	American Journal of Sociology 1982 Vol. 87 No. 6: 1340-1359
Homicides in the US increased following heavyweight championship prize-fights in a relationship that persisted after correction for secular trends, seasonal and other extraneous variables. The increase was found to be largest following heavily publicised fights.	American Sociological Review 1983 Vol. 48 (Aug): 560-568
Between 1973 and 1979 teenage suicides increased significantly following 38 nationally televised stories of suicide. The intensity of publicity devoted to the suicide stories was significantly correlated to its effect on teenage suicide rates	New England Journal of Medicine 1986 Vol. 315 No.11: 685-9

- ... In 1974, the sociologist David Phillips coined the term "the Werther effect" to describe imitative suicidal behaviour transmitted via the mass media. Phillips devised an empirical research programme to establish whether media reporting of suicide stories really did affect suicide rates. In over a decade of research, Phillips produced important evidence that supported the hypothesis that behavioural patterns in society can in fact operate as contagions.
- Phillips' methodological approach could be described as *quasi-experimental* in that his analysis was based on an experimental protocol, but he worked with exclusively historical data sourced in the real, uncontrolled, world. Using newspaper records and official suicide statistics, he identified a number of 'control periods' defined by the absence of front-page newspaper suicide stories. Using the suicide statistics from these control periods, he generated a number of expected suicide rates for a pre-defined selection of 'experimental periods' during which front-page suicide stories were published. Working with a null hypothesis that the front-page newspaper reporting of suicide stories had no effect on aggregate suicide rates, he compared the expected rates with the actual rates. After controlling for seasonal and other spurious effects, Phillips tested for significance between the two values, and by comparing a number of different experimental periods he was able to test for a correlation between suicide rates and the intensity of media representations.
 - Importantly, Phillips was not testing for the relationship between individual behaviour and media representations; rather he was testing for a relationship between suicide rates and media representations.
 - ... It is important to recognise that Phillips was testing for the replication of structural patterns in society rather than investigating the individual process of replication/transmission per se. In this way, his approach is an example of what might usefully be called *macro-memetics*, in contradistinction to the equally valid *micro-memetic* approach that currently dominates our paradigm.

- Following Phillips' research protocol, such a macro-memetic analysis can be broken down into a certain number of stages that together might outline a possible method for investigating the structural epidemiology of memes:
 - 1. Define the phenotypical expression/symptomatology that will be used to measure levels of meme infection (suicide)
 - 2. Measure the prevalence of meme infection over time within a given population (suicide rates)
 - 3. Measure the exposure rate within a population to this meme through a particular (mass) medium over time (circulation/viewing figures)
 - 4. Calculate an index of exposure intensity (exposure level multiplied by the share of total medium content (column length/no. of days on front page))
 - 5. Define a series of control periods where media transmission intensity = 0
 - 6. Define an experimental period where media transmission intensity > 0
 - 7. Regress meme infection levels during control period(s) to generate an expectation for the experimental period based on the null hypothesis that media representations of the meme have no effect on the incidence or prevalence of that meme
 - 8. Test for significance between the expected and actual results
 - 9. If expected and actual results are significantly different, test for further relationships (e.g., host similarity/correlation of intensity and suicide rates)
 - Such a research programme might yield results providing evidence to support the hypothesis that meme exposure partly determines the incidence and prevalence of meme infection. Put differently, Phillips' macro-memetic approach would help determine whether patterns of behaviour in society do in fact operate in a manner similar to that of contagions.

- A memetic approach, operationalised as *the epidemiology of social contagions in society* could build on research such as that conducted by Phillips, and could capitalise on the inability of current paradigms to adequately deal with the phenomenon of replication/imitation.

MEMETICS ON THE EDGE OF CHAOS, By Paul Marsden

- The memetic stance involves taking a 'meme's-eyes view' of the social world, and analysing social phenomena as if human agents were vehicles for these replicating

cultural traits. ... Apply such a memetic stance to corporate culture and management theory, and in doing so develop a broadly memetic understanding of organisations.

- ... Companies are both constructed and constrained by the patterns of beliefs and rules (memes) that produce behaviour, and ultimately determine commercial performance. To change the patterns of performance, it is necessary to change the patterns of beliefs and rules (both explicit and implicit) that determine that performance.
- Rather than adopting the conventional view that individuals are the hosts for memes, this "*unconventional perspective*" holds that companies should be understood as the proper hosts for memes. Embracing 19th Century organicism (Spencer 1969), the authors suggest that organisations can be understood "*as 'living', self-organising, self-maintaining entities*", and these entities are the proper hosts for memes. Specifically, the meme concept is introduced as a heuristic device for understanding the components (sets of beliefs and rules) of the patterns which define the organic company.
- Rather than adopting the conventional view that individuals are the hosts for memes, this "*unconventional perspective*" holds that companies should be understood as the proper hosts for memes. ... Organisations can be understood "*as 'living', self-organising, self-maintaining entities*", and these entities are the proper hosts for memes. Specifically, the meme concept is ... a heuristic device for understanding the components (sets of beliefs and rules) of the patterns which define the organic company.
- [An unclear] definition of the meme: "*An organism is coded via chemical strands of DNA, sections of which form genes, the smallest units capable of being copied. An organisation is coded via 'ideas and images of the mind', abstract strands of thinking, perception and language, the smallest units of which can be thought of as memes which may be interpreted as: the smallest element capable of being exchanged, with an associated sense of meaning and interpretation, to another brain.*"
- ... whilst we are the products of our memetic inheritance, we also have the power to shift the patterns, to rebel against the tyranny of the memetic replicators, in a world where small changes can have major effects.

MEMETICS AND SOCIAL CONTAGION: TWO SIDES OF THE SAME COIN? By Paul Marsden

- It is suggested that social contagion research, currently lacking a conceptual framework or organising principle, may be characterised as a body of evidence without theory. Conversely, it is suggested that memetics, now over two decades old but yet to be operationalised, may be characterised as a body of theory without evidence. [Propose] a memetic theory of social contagion ... social contagion research and memetics are indeed two sides of the same social epidemiological coin ... a call for their synthesis into a comprehensive body of theoretically informed research.

- The failure of mainstream social science to take ... social contagion evidence seriously is certainly in part due to the ... disorganised and incoherent state of the field.
- Not a fully blown theory, the memetic stance is more of a way of looking at the world, a set of guiding principles, and a useful heuristic, based on some hopefully important insight into the nature of the social world. Whether the memetic stance turns out to be an explanatory device in an evolutionary extension of folk psychology, or a proper theory of mind where memes are internally instantiated in the neural networks of our brains, is an issue that will one day have to be resolved empirically.
- So what exactly is the memetic stance? The memetic stance states that human condition is minimally defined by two selective processes operating in two different substrates, the biological and social ... This is because the necessary conditions for the evolutionary loop of replication, variation and selection are present in the two substrates. This is not contentious in itself, what is more contentious is that the memetic stance sees these processes operating at the level of what is being replicated, that is, the gene and the meme. Thus, the memetic stance involves taking a meme's-eye perspective and understanding of the social world, thinking not in terms of selfish genes, but selfish memes. Taking this memetic stance has allowed researchers to explain the spread of non-rational behaviour in terms of the fitness of that behaviour itself. Examples include altruism ... chain letters ... chain e-mail ... religions and cults ... political revolutions and war ... religious scriptures ... management practices ... media representations ... urban legends ... and consumer behaviour.
- Once we take the memetic stance, features of the world that are difficult to explain from the orthodoxy of traditional social science become non-miraculous and eminently explicable. The memetic stance can explain not only apparent design in the social world, but importantly it can also explain phenomena that seem to negate the omnipresence of individual agency in human affairs. Put simply, the memetic stance states that the reason why some social behaviour doesn't seem to make sense from the perspective of the individual is because we are looking at that behaviour at the wrong level. We are taking an anthropocentric or homuncular view of a social world that was created at least in part at a memetic level. Trying to explain the social world from the perspective of the individual is like trying to explain the movements of a car without reference to the driver.
- Taking the memetic stance involves, to use an overused concept, a true Kuhnian paradigm shift; just as evolution in the biological world evolves according to what is better (not best) for the gene in its environment, so too does the social world evolve according to what is better for the meme. The memetic stance involves describing, explaining and understanding social behaviour from this meme's-eye perspective. From the memetic stance "What makes this person want to do x?" becomes "What is it about x that makes people want to do it?" Social contagion can be explained by the memetic stance because culture has an independent evolutionary dynamic that is derived from the genetically evolved human capacity and predisposition to replicate culture. ... We have an evolved predisposition to replicating the behaviour of those around us. Successful social contagions are those elements of culture that operate as both stimulus and

response, and that are adapted to the evolved architecture of the human brain. No homunculus need be invoked, only evoked imitation.

- ... Memeticists could develop the social contagion research tradition of using the substrate neutral tools of epidemiology to assist their research programme. These tools could be adapted to provide useful information about differential incidence and prevalence of evolving cultural traits, as well as structure of endemic and epidemic features of society.

A STRATEGY FOR MEMETICS: MEMES AS STRATEGIES, By Paul Marsden

- Memetics organised around the interactions of thought contagions ... is problematic because that interaction is neither observable nor measurable. This simple fact renders the thought contagion metaphor both conceptually vacuous and empirically redundant. It is certainly not by performing arbitrary mathematical manipulations and endowing the objects of introspection with contagious properties that will improve the status of a partial and misleading metaphor. ... The thought contagion metaphor persists largely because of what could charitably be called a 'disregard' for linguistics and cognitive science.
- Dawkins has recently declared that he is "alarmed" that his readers have taken his memetic speculations at face value as a theory of culture ... and a number of leading evolutionary psychologists ... have also made known their scepticism as to the scientific viability of the whole memetic enterprise. Of course, the fact that the founding fathers of memetics have doubts about memetics, qua scientific enterprise, is no reason in itself to abandon research. But surely we should be addressing their specific concerns, and those of other evolutionary theorists, rather than burying our heads in outmoded pseudoscientific introspectionism.
- ... Meme theory built on the thought contagion metaphor is simply bad strategy for the establishment of memetics as a respectable and respected research enterprise. If memetics wishes to be taken seriously, it must first explicitly address the established theories that already seek to explain the object of memetics' own enquiry and demonstrate *theoretically and empirically* how the new memetic approach is superior. Growing memetics in an intellectual vacuum on a staple diet of partial metaphors is not only foolhardy, it is intellectual suicide.

THE LEARNING ORGANISATION MEME: EMERGENCE OF A MANAGEMENT REPLICATOR, By If Price and Ray Shaw

- Organisations and organisms are self-maintaining systems which spontaneously seek to preserve an evolved order. Both are enabled by replicators: memes or genes respectively. Whereas genes are the units of transmission of our biological inheritance memes are the units of transmission of our cultural inheritance. They cause organisations to settle into patterns, routines and habits of behaviour: manifestations of a particular memetic inheritance. These patterns enable the organisation but simultaneously limit its performance. Both systems share the evolutionary dynamic of adaptive radiation followed by stabilisation. Memetic examples include new markets, new technologies and new business ideas. Business theories and their derivative, managerial fads, are a class of memes.

THE SELFISH TEXT: THE BIBLE AND MEMETICS, By Hugh S. Pyper

- ... A hen as 'an egg's way of making another egg'.... An organism is a gene's way of making another gene ... *Western culture is the bible's way of making more bibles.*
- ... Dawkins becomes concerned to distinguish between a meme as a unit of information lodged in a brain and the phenotypic effects of that meme, such manifestations as the tune or the idea.
- Definitions are difficult, to say the least, in these areas. What exactly constitutes a meme or a culture defies classification and the recent literature on memes is bedevilled by shifting definitions and unsupportable generalisations and comparisons. Extravagant claims for the explanatory power of this concept have been made, including claims that the key to human self-understanding is in the new 'science' of memetics. ... Dennett elaborates the concept of the meme ... where he defines memes as 'self-replicating complex ideas which form *distinct memorable units*'. Even so, the concept remains notoriously fluid and therefore liable to abuse.
- Dawkins himself uses the 'mistranslation' of the Hebrew for 'young woman' as 'virgin' in the Septuagint version of Isaac 53 as an example of the potentially enormous phenotypic effects of a small change in DNA.
- The replicator must maintain its identity over time. Equally important, however, is its capacity to throw up variants which, when conditions change, may confer an advantage on the organisms which bear them. It is this balance between the ability to reproduce faithfully a particular variant but also to be able to produce variation if the circumstances favour it that confers reproductive success on any replicating system.
- Mere reproduction of a text as a physical artefact is not enough to ensure its continued survival ... Copies of books will only endure so long and the relative youth of even the earliest complete manuscripts of the bible bears this out.

DARWINIAN SOUP, By W.G. Runciman

- The word 'meme', popularised by Richard Dawkins in *The Selfish Gene*, has recently gained entry into the *OED* as 'an element of a culture that may be considered to be passed on by non-genetic means, esp. imitation'.
- The controversies are of two kinds. For some opponents of 'memetics' in any guise, the mere idea of it is totally misconceived, whether because (as the Reductionists argue) cultural evolution is really all about the workings of our genes, or because (as the Creationists argue) it's really all about the souls implanted in us by God, or because (as the Post-Modernists argue) no so-called theory of cultural evolution will ever explain it any better than any other so-called theory. There are also not a few anthropologists and

sociologists for whom the mere association of 'memes' with the name of Dawkins is enough to rule them out of mention in correct academic society.

- The disanalogies with natural selection are obvious, and Susan Blackmore is well aware of them. There aren't, literally speaking, lineages of memes as there are of genes, and memes, unlike genes, can be discarded by the people who carry them and replaced by others.
- But what is - or isn't - a 'meme'? Blackmore sensibly eschews any attempt to find precise 'memetic' analogies for genetic concepts like alleles, meiosis and so forth. But having reviewed some of the many conflicting opinions in the current academic literature, she concludes that the best thing to do is to 'use the term "meme" indiscriminately to refer to memetic information in any of its many forms; including ideas, the brain structures that instantiate those ideas, the behaviours these brain structures produce, and their versions in books, recipes, maps and written music'. This is not only confusing, but defeatist.
- But if 'memetics' is, broadly speaking, about the way instructions affecting phenotype are transmitted from mind to mind by imitation and learning, it is presumably worth drawing an explicit distinction between the instructions transmitted, whether visually, orally or in written form, by parents, teachers, peer-group members or role-models, and the behaviour which the instructions dictate. Nobody can deny that such transmission is happening every day. Why, then, should even those whom Daniel Dennett calls 'Darwin-dreaders' object to the adoption of a single word for whatever specific bundles of instructions affecting phenotype - whether encoded in gestures, speech, writing or any other medium - do in fact guide the behaviour of the members of different cultures or sub-cultures?
- 'Memes' can include discrete units of memorable information (whatever they are) within the totality of values and beliefs which guide our cultural behaviour, as well as mental representations (however they function) of recipes, drawings, musical scores, prayer-books, folk maxims, manuals of etiquette and so forth. The different individual 'cultures' of the human populations in the ethnographic and historical record then consist of sets of related 'memes' (Blackmore calls them 'memplexes') which have been handed down sufficiently widely and accurately over a sufficient number of successive generations to amount to a definable cultural tradition.
- If 'memetics' is to contribute anything significant to what is already well known to anthropologists, sociologists and historians of religion, it will have to be by identifying specific components of different religious 'memplexes' whose probability of replication can be shown to have been enhanced by specific features of their carriers' environment - a rewarding task, but a very difficult one.
- Only detailed and wide-ranging re-examination of the relevant ethnographic, historical and archaeological evidence for the heritable variation and competitive selection of clearly identifiable 'memes' whose spread can accurately be traced and functions convincingly specified will turn 'memetics' from a project into a science.

DARWINIAN PROCESSES AND MEMES IN ARCHITECTURE: A MEMETIC THEORY OF MODERNISM, By Nikos Salingaros and Terry Mikiten

- This paper applies the theory of memes to the field of architecture. Two main points are argued: (1) Darwinian processes (combining variation and selection) are important to architecture; and (2) the specific case of modernist architecture corresponds to a 'parasitic' meme, which has spread in spite of its being non-adaptive for the people that make use of modernist buildings. These two theses are logically independent, though both are necessary to present a picture of how architectural styles propagate.

MEMECOSYSTEMS: ARE ANIMAL MINDS SUITABLE HABITATS FOR MEMES? By Brent Silby

- Memes are best thought of as sets of instructions that can be followed to produce behavior ... Instructions can be encoded in a number of formats, including:
 - Musical notation,
 - Written text,
 - Visible (or vocal) action,
 - Connectionist networks such as the neural structure of the brain.

EVOLUTION OF TECHNOLOGY: EXPOSING THE MYTH OF CREATIVE DESIGN, By Brent Silby

- Many thinkers have resisted the idea of memes on the grounds that it is not possible to determine exactly *what* the meme is. We know that it is an idea that replicates, but how can we *point* to a meme? How can we isolate a memetic unit? This is a valid question. After all, there seems to be big differences between memes such as the first four notes of Beethoven's fifth symphony, the phrase "You're damned if you do, and you're damned if you don't", and the behavior of shaking hands. How can each of these be considered to be single memes? A similar problem arises when scientists talk about genes. There is no real gene 'unit'. Genes are packets of information that are encoded in DNA. Distinct genes can vary markedly in length. The same goes for memes. Memes are best thought of as packets of information that can be encoded in a number of different mediums. They can be encoded in the complex neural architecture of the brain, and they can be encoded in magnetic patterns on a hard-drive. A memetic 'unit' can be described as a *self-contained information packet that reproduces*. So, the first *three* notes of Beethoven's fifth symphony do not constitute a meme because it is not a self-contained information packet that reproduces. The *fourth* note is required to complete the reproductive unit. Of course, the question of the rest of the symphony now arises. Is it made up of a multitude of four note units? The answer is no. The symphony *is* made up of a vast collection of memetic units, but they are all different lengths. The entire symphony constitutes a memplex that has good replicative power, but many of the individual memes would not make it alone. Some do, however -- you often find small pieces of music reproduced in other work --

but for the most part, the memes are dependent on their counterparts in the memplex for survival. It is possible that the memes that comprise the fifth symphony memplex were common in Beethoven's day. He was undoubtedly influenced by the tunes and musical themes of his time, and these would have found their way into his work. Even though they would no longer survive on their own, they manage to survive by being a part of the large symphonic memplex that continues to reproduce.

A MEMETIC ANALYSIS OF POLICY MAKING, By Hans-Cees Speel

- We argue that, in memetics, concepts are often still unnecessarily ambiguous and that thus the establishment of clear definitions is important.
- **Memes:**
 - Pieces of data that are a) copied from individual to individual without too much alteration, or B) that are interactors.
- **Interactor:**
 - An entity that interacts in an arena, where this action results in differential perpetuation of memes into a retention system.

THE REPLICATOR: A MISNOMER: CONCEPTUAL IMPLICATIONS FOR GENETICS AND MEMETICS, By Mario Vaneechoutte

- ... The use of replicator for gene or meme is twice erroneous: they are not self-replicators (remark that 'replicator' is generally used to have the implicit meaning of self-replicator) and they even are not processor-replicators. Genes and memes are replicates or bits of replicable information. For memetics this means that we have to ask the question why some information is replicated more successfully by replicators like human minds and not why they replicate more successfully than other memes. This [is the] more scientifically correct approach ...

MERGERS AND TAKEOVERS; A MEMETIC APPROACH, By Ed Vos and Ben Kelleher

- This paper constructively diagnoses problems within the current merger & acquisition (M&A) theories and provides an alternative theory of corporate behaviour. We contend that humans are the hosts for a replicating entity known as 'memes'. Since finance based motivational studies on M&A activities have not established that this activity 'adds value' to the acquiring firm, it is our thesis that certain managers gain power through mergers and acquisitions. Thus, M&A from the point of view of the acquiring firm can be seen as driving the evolution of ideas, shaping the flow of technology, information, and tastes rather than as 'value adding'. In simple terms, managers (the meme holders) use mergers and acquisitions to enhance their power, and in gaining this power managers

unconsciously provide an improved medium through which their memetic `stories' may be replicated.

CRITIQUE AND DEFENSE OF MEMESIS

By
Onar Aam
May 1996

In his article "Memesis Critique" Richard Barbrook [please see below] presents a massive critique of memetics and memesis. While great portions of the article are based on a rather uninformed and projective understanding of memetics Barbrook does make some valid points. One of them is:

"The other major error in the Memesis statement is its use of dodgy biological analogies."

Memetics as an idea

Barbrook is correct that the concepts of memetics are not rigidly scientific. Currently memetics is little more than a pop-theory. Based on this many people draw the erroneous conclusion that memetics is a bad idea. This is not the case. The problem lies in the methodology and support fields rather than in the idea itself. Indeed, Darwin's own idea of biological evolution was at the time he conceived it nothing more than a promising idea. The reason it later became a rigid scientific fact is that Darwin was able to base his idea on existing scientific disciplines: botany, paleontology, geology and taxonomy. (Later also biochemistry and genetics) Without these disciplines as foundation Darwin's nice idea would be just that: a nice idea. Therefore Barbrook is only partially correct when he states that:

"Crucially, evolutionary theory was conceived in the first truly modern society: Great Britain. The rapid economic and social changes taking place in this first industrial society enabled Darwin to understand that nature itself was also in flux."

This alone was not enough. The crucial element which distinguished Darwin's idea from other neat ideas was that he had very respectable disciplines to back it up. As of now memetics lacks such supporting disciplines. This is partially due to the lack of coherence in the social sciences and partially due to memetics' reluctance/inability to coordinate its project with existing fields. I can't imagine any serious scientist who would object to the above critical characterization of memetics.

As a scientist who have been working a lot with these ideas I feel competent to outline a sparse list of fields which memetics should be developed upon: behaviorist sciences, phenomenology, communication theory, systems theory, Artificial Sociality (ASoc) and cognitive sciences. This list is far from complete, but it illustrates the diversity that is required to turn memetics into a science.

Ontology

Genetics has a primitive, but well-defined ontology. The ontology of memetics on the other hand is a disaster. It is a disaster because most people in the field do not even realize that there is a problem, much less what the problem is. Even so I will try to briefly summarize it.

If you ask a geneticist what a gene is he can give you a quite elaborate technical definition. If you however ask a memeticist what a meme is she can give you a lot of examples, but no coherent definition. Typical examples of memes are catch phrases, pop songs, ideas, fashions etc. The first problem is that of substance, what memes are "made" of. Note that the above list of examples appear in a wide range of media and substances: sound waves, CD's, books, memories, computers, clothes etc. As you can see memes appear in virtually any medium or substance. The only thing these seem to have in common is "information". Information -- or rather culturally transmitted information -- is therefore the substance which memes are made of. This is how far traditional memetic ontology extends.

Now, if the meme-concept is to have any scientific meaning whatsoever there must exist a consistent method of measurement. Herein lay a major problem. How do we measure memes? Let me give you an example to illustrate the problem. Suppose we have a "red scarf with blue dots" meme. Then after a while people come up with variations of this fashion. They start wearing blue scarves with red dots, or a shirt instead of a scarf, stars instead of dots etc. Are these mutations new memes or are do we have a cluster of memes? We wouldn't know because a taxonomy for memes does not exist.

Consciousness

Another serious problem is what role consciousness plays in memetics. In this matter the memetic community is approximately divided into two. 1) Those who ban consciousness (the behaviorists) and 2) those who haven't reflected over the role of consciousness. Behaviorist memetics is definitely the branch which has the best developed taxonomy. To a behaviorist memes are primarily stored as habits, and habit formation is something behaviorists have scrutinized for a long time. But unfortunately this method has great problems dealing with mental objects such as ideas. Surely ideas are stored in the form of habits, but without a consciousness observer included in the model it is impossible to determine the structure of the idea. Hence measuring ideas is virtually impossible with current behaviorist methodology.

In any case, no matter which branch they belong to few people in the memetic community address the problem of consciousness. In my opinion understanding the machinery of consciousness is as important to memetics as understanding the machinery of the cell is to genetics. If this is true then the realization of a memetic science is far away.

Emergence: the problem of nurture vs. nature

One of the places where the role of consciousness comes most into play is in the grey zone between emergence and replication. Consider the following scenario: suppose a woman is called Sherrie Berry (This is a real person!). Many people who meet her comment that her name

reminds them of cherries. Even so this information is not something that has spread culturally. People seem to come up with this idea independent of each other. So then, is the cherry-association a meme or not? It is not a meme. What we have here is an example of “emergence”. That is, the arising of a pattern due to the particular structure of the systems with which Sherrie interacts. This is equivalent to the emergence of e.g. waves. If you splash your hand in the water you will create a wave. If you splash it again another wave will emerge. But the waves you create are not replications. They are rather the internal dynamics of the system at hand. This is how it is with the cherry-association. Many people get the same association because they have common biological associative cognitive machinery that behaves similarly, not because the association replicates.

The complexity of this problem is perhaps made clearer if I say that consciousness is precisely a field of emergence. The above example is, of course, simple and obvious; but let us consider more complex phenomena. In the last century racism has popped up in suspiciously many places in one form or another (social Darwinism, scientific racism in the US and Soviet, Nazism in Germany, apartheid in South Africa etc.) A natural question to ask then is if this perhaps is a culturally replicated pattern, i.e. a meme. But as in the above example we will find that these ideas have often popped up rather independently of each other. Besides, why have racism become so popular and not e.g. shoe making? It is as if racism "strikes a chord" in many people, as if it emerges rather than replicates. Or that it also more easily replicates because it lies people's hearts more closer than shoe making? What we have encountered is the problem of human nature. Humans are by nature culturally discriminating beings and ideas of racism will therefore tend to pop up more often than others. Just like waves tend to arise in water, racism tends to arise in humans that encounter foreign cultures.

Another example to illustrate the point is the history of philosophy. If you compare the ideas of the many great thinkers you will often find extremely similar ideas across centuries, yes, even across millennia. Again these ideas often arise independently of each other and so again we are dealing with emergence rather than replication.

Thus, the problem that memetics has to deal with greatly resembles that of nurture vs. nature. I.e. is the behavior of people environmentally encoded (i.e. cultural transmitted) or is it biological (i.e. emergent)? The answer is yes! (i.e., both). There is an intimate interaction between emergence and replication. They are inseparable concepts.

This makes the task very difficult for memeticists. Ultimately memeticists have to map the structure of human nature in order to fully understand memetic evolution.

System and Form

The problem of emergence is perhaps the best illustration of the ontological problems that memetics are up against. But this far from concludes the list of problems. In my opinion the most pressing practical and theoretical problem is that of system and form. The biological world is not just a soup of living creatures, but a highly structured dynamical system with many emergent forms and archetypes. If culture is an evolutionary arena then we should expect to see the same complexity and diversity of forms and archetypes as we see in the biological world. Naturally a

theory that tries to capture the evolutionary structure of culture should reflect this complexity. Does memetics reflect this complexity? No. The key structure of memetics is based on the concept of the selfish gene coined by Richard Dawkins. The problem with this idea is that it innately reduces the complexity of the biosphere by placing too much importance on the gene. The cell, the multi-cellular organism, the species, the ecosystem or in general the “organism” suffers badly under the selfish gene idea. Even so the idea is viable biology since there exists a multitude of biological fields that prevents the idea from going astray. But in the cultural sphere the idea stands alone without fields to support it or correct it. Therefore the idea has gone astray in the case of memetics. Whereas the virus is generally considered an amusing but peripheral phenomenon in biology, memeticians use it as their fundament. This in my view is the single most important problem with memetics. If a biological analogy should be used as a fundament for an evolutionary discipline in social science then that analogy should be built on well-established biological concepts rather than on a peripheral concept like the selfish gene. In the short term the selfish gene idea may have more popular appeal, but in the long run this is going to insure the death of memetics as a science.

The Defense

Above I have presented a massive critique of memetics as a science. But memetics as a science is something totally different from Memesis as an idea. I will therefore present a defense of this vision. Barbrook neatly summarizes the essence of the Memesis statement:

"The central error of the Memesis statement has become obvious. It regards machines and information as autonomous things outside our control."

However, instead of accepting and embracing the idea he denies it:

"Yet, in reality, both technology and culture are expressions of the social relationships between individual humans."

What Barbrook fails to realize is that technology outlives us. Thousands of years ago individual humans started writing their thoughts and ideas down on paper. Those people are now long gone, but people today still write down their ideas and thoughts on paper. In other words, even though technology is an expression of the social relationships between people it tends to outlive the individual. Therefore inevitably technology and culture are to some degree autonomous things outside our control. Barbrook is wrong when he states that Memesis reiterates “the old McLuhanite lie that technology shapes our minds” because that "lie" has a ring of truth to it. The reason is that technology has a historical tendency to be used to promote one culture. A culture with a superior technology also has the power to take over other cultures. The other cultures have two options: 1) surrender and perish, or 2) adapt to the technology of the enemy and survive. Since history is written by the survivors history is full of arms races, and in the long run the only winner is technology. As such we are undeniably slaves of technology whether we like it or not.

Arms races are just one example of technological autonomy. A more peaceful example is Internet. Internet will probably outlive us all, and it certainly supersedes the power of

governments. No single government can control Internet. And as the net becomes increasingly more important for inter-cultural communication and business the only opportunity is to embrace it.

The following statement by Barbrook was meant as a rhetorical question but I will take the liberty to answer it:

"But, if there is active human involvement in the construction of cyberspace, how can technology and [memes] be autonomous forces outside our control?"

In my view this question is best answered by comparing culture to the multi-cellular organism. Like cells constitute the multicellular organism, people constitute culture. Just like the cells in an organism have a common genetic material, the people in a culture have a common language. Let me now rephrase Barbrook's question in terms of the organism-analogy: If there is cellular activity involved in the construction of the multi-cellular organism, how can it be an autonomous entity outside the control of individual cells? In biology we have no problems viewing the multi-cellular organism as an autonomous unity built up of other autonomous unities. Why then should the idea of culture as autonomous be any more problematic?

Conclusion

As of today memetics is very far from fulfilling the requirements of a science. But I think it is just a matter of time before most of these problems have been resolved. The end result may not be as the current memeticians envision it, but it will certainly be an evolutionary founded social science. The lacks of current memetics does however not discredit the idea of Memesis, or what Francis Heylighen would call a Meta-System Transition.

MEMETICS AND MONTAG

Five philosophical questions put on the web at 8 October 1996

You can refer to this interview as

Speel HC, (1997) Le idee come entita materiali. In: La Trasmissione delle idee. Montag, statica e dinamica delle idee.

Antomarini, B; Biscuso, M; D'ancunto, G; Gozzano, S; Ferretti, F; Traversa, G (ed.). 35-39.
Edizione Fahrenheit 451 Roma

This interview is published in MONTAG. A philosophical series of 8 books in Italian. There will appear two other interviews here when they become available. The Editors are young doctorates: Brunella Antomarini, Francesco Ianneo, Francesco Ferretti, Simone Gozzano, Guido Traversa, Giuseppe D'Acunto, Massimiliano Biscuso. Publishers: Federico Scanni and Catia Gabrielli. Publishing house: Fahrenheit 451, Campo de' Fiori 44 - Roma.

Montag is the hero of the novel Fahrenheit 451 (R. Bradbury), whose plot deals with a fictional society where books are all burnt. Montag, together with other clandestines, keeps the contents of books in mind in order not to lose them.

Brunella Antomarini at Brunella@uni.net, invited me to answer the five questions below. Questions about the volumes of MON- TAG can be mailed to her. The first volume is scheduled this year, but alas it will be in Italian only. Therefore I have the original English version right below.

Questions:

1. Is the memes' theory a scientific theory? That is, could we say it is an analogical theory - meant to arrive to a biological law similar to the genetic one - or a metaphoric theory - using the gene-theory as just an explicatory aid?
2. But, according to this perspective, isn't the act of knowing totally replaced with the memes' representation of knowledge? If even knowing is just memes resulting stronger than others, isn't this theory itself such a representation? What is left of the relationship with concrete things?
3. Isn't the model of natural selection - and that of mutation - a weak means to explain the way fast-changing ideas are spread? Doesn't intention have a more plausible role in transmission of ideas?
4. What kinds of entities are memes? Are they material entities entering minds? If there's anything outside the mind, which is not biologically verifiable, how can they ever enter the mind?
5. Do memes imprint themselves on the brains? If so, isn't their diffusion intentional?

Question:

1. Is the memes' theory a scientific theory? That is, could we say it is an analogical theory - meant to arrive to a biological law similar to the genetic one - or a metaphoric theory - using the gene-theory as just an explicatory aid?

Answer:

First of all, let us look at the question. In general metaphor is used as being broader than analogy. In this way analogy seems to refer to a law in biology, and metaphor to an explanatory aid. I think it can be used as you please. In my opinion biology does not have many laws, and certainly no laws in the way physics has them. But aside from this, my efforts are not to arrive at any laws of biology. Memes are in the realm from behavior to thought so it depends how broad you take biology to be.

I think that in the common sense of the word, they are not in the realm of biology, since genetics has little to do with memes, apart for the fact that the things memes are in, are biological, and that parts of these things (things are organisms) can be determined by genes to a large or small extent to take up memes without too much interference by intentions.

I think that the most positive way to look at it is that the memetic perspective, both the virus-metaphor, and the selective metaphor, can be an aid to understand otherwise difficult to understand phenomena. That would be more metaphoric I think. This does not mean that the theory about the structure of thought is very analogical to biological theory, especially the Darwinian Theory. By the virus metaphor I mean the memetic perspective that Dawkins takes, where memes spread without much resistance.

By the selective perspective I mean the perspective where there is a focus on selection of memes; people can and do resist ideas, especially when those ideas prescribe them to behave in ways they don't like, or if those ideas tell them to agree on morally wrong ideas, in their judgment.

Question:

2. But, according to this perspective, isn't the act of knowing totally replaced with the memes' representation of knowledge? If even knowing is just memes resulting stronger than others, isn't this theory itself such a representation? What is left of the relationship with concrete things?

Answer:

No, the act of knowing is not totally replaced with the memes perspective of knowledge. The human is the one who does the knowing, the meme is replicated. It is possible that humans accept and use memes without knowing they do, but still the memes do not do anything. My phrase to state this is that 'humans do, memes don't'.

The theory of memes is such a representation, but memes are not only representations. In my opinion memes can be 'ways of thought', which can connote to a way to represent. But memes

can also be behavioral patterns. Mothers teach children, sometimes quite intentionally, not to steal money or candy [and so do fathers]. The pattern of behavior, or rather the forbiddance of a pattern, is replicated to the child by punishment, or otherwise. That is not really a representation.

In the same way, songs in the hit parade are replicated, and they are not a way of representation. In the same way, the attachment of emotions to certain stimuli is replicated by movies. We all cry if we see some scene from a touching movie. First of all because it reminds us of emotional events, but later this can be strengthened by the fact that everybody knows the movie, and the reference to that scene can become a 'sign' to feel the emotion. The most fascinating examples for me are the way memes shape government processes. Ways of financing are replicated, for instance because the actor that gives money requires you to order your finances in a specific way, so he can compare different requests for the money he supplies.

If you don't follow his instructions, he will not give you money. I am still thinking about more examples, and what the memetic perspective can add to what I already knew.

Question:

3. Isn't the model of natural selection - and that of mutation - a weak means to explain the way fast-changing ideas are spread? Doesn't intention have a more plausible role in transmission of ideas?

Answer:

The model of mutation is not weak. Let us look at biology. We have all kinds of mutations: point mutations are the first kind that people probably will associate with mutations. But we have chromosomal mutations, we have inversions, we have crossing over [technically not really a mutation], there are processes in which chromosomes are doubled, where double chromosomes are cut up again, etc, etc.

There are a lot of mutations, some very strong in changing genes, and some not. So I doubt if the model of mutation is weak. Take a textbook like Susuki, an introduction to genetics, or some title like that, and read it! You will be amazed how much of mutation is possible.

And now that I am talking about books, no philosopher that thinks about memetics can go through life without reading David Hull. Because David Hull is one who does not write too much, he writes his things with a great feeling for clear definitions, and knows about biology, and memetics.(Footnote about Hull). Now to the 'way fast changing ideas are spread'. First of all memes are not only ideas. But secondly the question is twofold; mentioned are spreading memes and fast-changing memes. These are two very different matters.

In populations of bacteria genes can spread very fast from individual bacteria to other bacteria, for instance by plasmids [little circle-shaped pieces of DNA, that have no direct function in mitosis etc,].In the same way viruses can spread very fast through a host population. So this analogy is no problem.

Fast-changing memes are another matter. They are the thing you focus on when speaking about mutation-types. Ideas can stick together in complexes that are copied from individual to individual in one complex. That is the idea of a meme. But memes can be shuffled with other memes, in the brain, for some purpose, or without clear purpose. It is clear that the mechanisms working in this are different from the mechanisms of genetic re-shuffling. In many ways that are fundamental. That should be clear. But is it this process more extensive, are memes more radically altered than genes? I do not know how I should measure two processes that are so different in their mechanisms. Especially since we know so little about how ideas are processed in brains [the mind-body problem].

Intention, I would say, does play a role, but the question is strange. Tell me what intentions are; tell me what free will is. There are libraries full about these questions.

Second, as mentioned, memes are not only ideas.

Ideas can be re-shuffled by intentional thought. But they can also be re-shuffled by rather unconscious processes, That is, we normally don't know how we instantly see that ideas don't fit together. We don't know how creative processes work exactly. Should we call that intentional?

Another example. Do we choose what we see as good and bad? Do we really choose what we think of as 'proper', or 'morally good'? I think we have little choice in that. We seem to copy what we see as good from our parents, or from the papers. Furthermore, we do not think about the dichotomy of 'good and bad', we just use it. Why don't we use very good, a bit good, a bit worse, a bit bad, very bad, and dead-evil? Why do we use a dichotomy, and not a threechotomy, or more numbers?

We do not choose; we copy. And we keep doing that mainly because we do not see that we could choose. So do intentions play a part in memetic evolution? Yes, they do, but often they don't. Is it impossible for intentions to play a part, where they don't at a certain moment? Probably not, but still it doesn't happen as far as I can see. By the way, memes are of course transmitted by brains, along with some other things, but we cannot think that we automatically have intentional influence on what our brains transmit. The things brains do are not always intentional.

Question:

4. What kind of entities are memes? Are they material entities entering minds? If there's anything outside the mind, which is not biologically verifiable, how can they ever enter the mind?

Answer:

I think they are material entities. I say think, because I don't know how thoughts in general are located or translated in the brain, in patterns, material structure or anything like that. I think nobody knows. I believe that memes are in some way material, meaning that there must be a way in which memes, like any other thought, memory, etc are somehow stored in the brain. They are given a meaning, in the sense that they are connected to an environment of other thoughts, or at least concepts in which they make sense in the meaning of memes being ideas.

If memes are behavioral patterns that are learned, without a necessary translation in words, the storage could be different, or not, I do not know that. One thing is for sure, behavioral patterns, are copied by means of learning processes for instance from parents to children. If you teach your child not to be rude, you are teaching him a meme. If you do that by explaining it in words, you use words and thus ideas to help the copying process, if you just slap him if he does something wrong, as in the way you train dogs [no intention meant to say that you should] ideas are not needed, and straight conditioning takes over from words as memes. In this sense memes are not only a way to comprehend, but are material [if you include pattern as material] entities, that are real in a biological sense.

The question arises here if that is all they are. I think not. As in a biological theory, the way we describe what memes are is a method of comprehension, like any theory, and thus the theory of memes, or theories of memes are a way to structure phenomena in the minds of scientists or any other humans that think by means of theories. I do not think that one excludes the other.

Question:

5. Do memes imprint themselves on the brains? If so, isn't their diffusion intentional?

Answer:

How can memes enter minds? Well in the same way that sound enters minds. In the same way in which light enters minds. How? I think nobody knows. In all these cases the question is relevant, but I am not sure someone has the answer. In my book, the question should not be how it enters minds, that is, by the senses, but how the hell it is translated into understanding. How do we know what sound means? How do we interpret light patterns, when a big lion attacks us? How do we know that there is a lion in a case when somebody tells us? How is it that we understand those words, and are careful to stay away from the bars even if we cannot see that lion right away? I don't know. I do know that we can, and thus think there must be a way we do that.

Are there intentions involved? In general we over emphasize that. If we see the lion without knowing that he was there, and we were dangerously close, we would be instantly scared, and that memory would stay with us for a while. So the brain can be seen as being more ready to memorize some events, rather than other ones. But do memes actively imprint themselves?

I think not. They are imprinted because we interact with other humans, and are susceptible to their influence. But memes themselves are just sitting, being more, or less copied, dependent on the copying processes that humans are involved in. Does that mean that we are always intentionally copying? No, I don't think so.

A REPORT ON THE CONFERENCE: “DO MEMES ACCOUNT FOR CULTURE?”

Held At King's College, Cambridge

By

Robert Auger

Department of Biological Anthropology

University of Cambridge

CAMBS CB2 3DZ, UK.

rva20@cam.ac.uk

The following report summarizes the issues which arose in the workshops associated with the King's College conference on memes held in June 1999. It is organized along the general lines of academic disciplines, since that is the way in which the workshops were arranged. Details of a forthcoming book deriving from the conference (including a chapter by Boyd and Richerson) can be found at: <http://www.cus.cam.ac.uk/~rva20/Darwin.html>.

1. Evolutionary Biology

Given its origin in the work of the zoologist and evolutionary theorist Richard Dawkins, the memetics literature has continued to exhibit a strong flavor of evolutionary biology. Many of the problems with pursuing this line of research therefore tended to arise from consideration of memes as analogous to genes -- that is, as cultural replicators.

Where are memes? It was generally agreed that the concept of memes should not be restricted to being only thoughts or behaviors or artifacts, but should be generally conceived (i.e., substrate neutral) for now. The possibility that it is behaviors rather than ideas which replicate was not specifically considered, although that is a position adopted by others within the memetics community (e.g., Derek Gatherer, William Benson). David Hull forcefully argued, however, that definitional uncertainties should not stand in the way of progress; it certainly did not in the case of genetics during the first part of this century.

The relationship of memes and genes: It was argued that memes can certainly influence genetic evolution. One need only think of lactose intolerance (an example discussed by Kevin Laland), where cultural practices (such as drinking milk) influence gene frequencies in a group. Likewise, genes may determine meme frequencies, if indirectly, through psychological biases against the adoption of some kinds of beliefs or values. The general consensus was that both replicators should be seen as coevolving in potentially complex ways. It has been a failure of some work in memetics to believe that memes operate without constraint.

Mention was also made of the immune system as another replicator system, acting at a different temporal and spatial scale (within the lifetime of a single organism, and confined to that body). The implication is that we need not rely only on the gene analogy to understand cultural replication; a variety of replicator systems exist, the investigation of each of which can provide

insights and heuristic principles for memetics, as well as a general awareness that there is likely to be more than one way to accomplish any evolutionary goal.

A major problem -- which many adherents admit to troubling over for a long time -- is establishing how the genotype/phenotype distinction might work for memes. This functional difference in the genetic system has been generalized by Dawkins and Hull as the replicator/interactor distinction. Although it is possible for a replicator to serve both as replicator and interactor (as in the case of a ribosome, for instance), it is generally considered unlikely to persist, if only because replicators and interactors have fundamentally different roles to play in the evolutionary drama (as store of information and as survivor/transmitter, respectively). It is usually inefficient for the same entity to play both roles, so a competitor system with greater specialization would almost certainly win out in an evolutionary race, if only because a more specialized replicator would likely be more robust in its ability to duplicate itself. So it seems memeticists must develop a notion of a memetic phenotype, or "phemotype." While there are a number of contenders for this role, none has achieved a widespread tip of the hat.

Part of the problem with developing a rigorous notion of a memetic interactor is coming up with a criterion which surely identifies it as distinct from its progenitor, the memetic replicator. A related example is the prion: is this protein a replicator or interactor (or both)? David Hull put forward one criterion for making this distinction, which is generalizable regardless of substrate and replicator system (and thus a candidate for Universal Darwinism): the relative difficulty of reconstituting the replicator from an interactor. This is a generalization of the Weismannian notion that you can't go "backwards" from protein to gene. This inability arises because there tends to be some slop in the production of phenotypes: genes don't code for one phenotype, they code for a reaction norm, thanks to the impact of environmental conditions on development. So the relationship between replicators and their material instantiations is not simple (i.e., not one-to-one). This implies that information will be lost in the translation from meme to phenotype. It is this loss of information which makes the project of "reverse engineering" (or inferring the instructions from the product, as Susan Blackmore puts it) so difficult.

If one allows that memes can be present in artifacts, then memes such as ink on paper can be replicated with very high fidelity: using photocopiers, we have direct replicator-replicator reproduction, and consequently no loss of information. However, many memetic replication cycles seem to involve stages of translation from one form to another, and hence some information leakage. In particular, more "traditional" memetic life cycles involve brains. If a meme must pass through someone's head, the general inability of bits of brain to duplicate themselves directly means that they must travel between hosts to replicate. But to do this, they must be translated into another form for social transmission -- for example, as bits of speech -- since bits of brain don't themselves make the journey from one head to another.

The first aspect of the problem is that, per the above argument, such phenotypes are compromised as message carriers. This information loss means there must be a reconstitution of the message by its receiver: this is the famous Chomskian "poverty of the stimulus" argument concerning linguistic message-passing. But if there is significant reconstruction of the informational content of a meme by each host brain, then the likelihood of message replication is low, thanks to the vagaries of how each brain processes in-coming information (due to the

different background information individuals have acquired, the inferencing algorithms they use, etc.).

One way out of this problem, suggested by Dan Sperber (who also brought this problem to our attention), would be for the brain to have a general decoder -- a utility enabling it to reliably infer the intention of the sender, and hence the substance of the message. In fact, this is what the much-lauded "theory of mind" module is likely to be for (although this, in itself, is contentious; most cognitive scientists believe agents reason upon others' minds as a special application of "instrumental reasoning" with special application to social world, rather than granting such a capacity a special modular status). In this view, brains have evolved filters to assess the utility of information coming in from the social environment to keep us from rapidly being swamped with bad information (i.e., duped into stupid behaviors by people with ulterior motives). This normalizing inferential machine might also ensure the replication of memetic material during social transmission. However, its operation is unlikely to be perfect, so a high mutation rate remains a potential problem.

The need to communicate memes between brains also introduces another problem. If such psychological normalization of memetic inputs is important for communication to be successful, then memetic information is not, strictly speaking, inherited because it is not passed from person A to B. Instead, the similarity of socially-acquired information between individuals has another cause: inherently structured inferential processing by the brain. These reconstructive processes depend on a long history of genetic selection on the human cortex, not the passing of information from person to person in cultural lines of descent. In effect, the cause of the similarity between the information in A's and B's brains is thanks to evolutionary psychology, not memetics. Since the causes are different, one can expect the population-level dynamics (e.g., rates of mutation, types of selection) to also be different. This creates a fundamental problem for memetics as an inheritance process (the most general view on memetics).

Dan Dennett pointed out, however, that the memetic process -- even if dependent on error-correction routines in the brain to produce cultural similarity of beliefs and values -- still confers an evolutionary advantage. This is because the same information is acquired through transmission-plus-correction more efficiently and cost effectively than individual learning through trial-and-error could have done. Further, error correction is an important aspect of genetic inheritance as well, so replicator systems can operate with such assistance without having to be called something else.

It was also noted by Susan Blackmore that Dan Sperber's reasoning leads to the expectation that, if there is a cultural replicator, there should also be selection for improved mechanisms for its transmission over time. In this way, the reliance on reconstituting information from local resources each iteration would be reduced and the proportion of information actually being transmitted increased. Her presumption is that this is indeed what has happened during the major transitions in cultural evolution, such as language, writing, and computer-based communication. But whether these have increased the transmissibility of memes, or merely their copying fidelity, remains to be determined.

A somewhat different view of memetics was presented by Liane Gabora. She takes her cue from neuroscience and complexity theory. More particularly, her critique of the replicator perspective is that memes do not function in isolation, but as parts of a complex conceptual network or worldview; this should be the basic level at which cultural evolution is analyzed. In Gabora's vision, the tendency to see memes as discrete, identifiable units is problematic. As parts of the brain, memes are intimately involved in highly distributed, highly structured and interconnected networks of neurons. Therefore, the means by which they are stored and evoked are highly contextualized. So, memes spend most of their time as parts of streams of thought which are continuously renewing, revising, and reassessing the constituent memes. It is the analysis of these more holistic streams of information which should be our primary focus. This can be accomplished, Gabora argues, along lines she has pursued in her own work.

Initially, Richard Dawkins argued it was important to consider the evolution of memplexes such as religious doctrines. What happens if some component of the complex is missing? Does its ability to function degrade significantly? Memplexes are another instance of a transition in evolutionary complexity, which should be approachable using "major transition theory" as it is being developed by Eoers Szathmary, John Maynard Smith, Richard Michod and others.

2. Psychology

Another major set of issues concerns the psychology of memes. The question which dominated discussion in this workshop is whether memetics can proceed without a clear idea of what kinds of transformations memes undergo during storage and retrieval by brains. Can memetics leave the brain as a black box, and deal only with social transmission aspects? The virtue of ignoring psychology is that we can simply talk about inheritance processes at the population level and not worry about something we don't know too much about anyway: how the brain processes information. On the other hand, if memetics disregards psychology, and there are major transformative processes at work in the brain, then memetics is only explaining part of the cultural evolutionary process, and may therefore "get it wrong." It was felt by some (particularly Rosaria Conte) that no social theory, including memetics, can succeed without a proper psychological underpinning.

Related to this question is the relationship of memetics to imitation. Two interconnected questions pop up here: First, Does imitation require a complicated brain to do? This issue is important because it determines who gets to have memes: only complex intentional agents like people, or more lowly creatures without cortices, such as birds? Many (including Henry Plotkin) argue that there is no consensus concerning the psychological mechanisms of imitation. This is significant because, as Rosaria Conte says, you cannot define imitation without reference to the mental abilities involved, because using behavior as the sole criterion leads to confounds. For example, automatic contagion (such as yawning) is direct phenotypic copying without the inferencing of mental contents. Counting contagion as a kind of imitation suggests that agents don't need to correctly infer another's intention (plus her beliefs and needs, etc.) in order to adopt or imitate her behaviors. What psychological resources imitation demands remains an open question.

Second, Should memetic transmission be restricted to imitation? Susan Blackmore restricts memetics to cases of imitative behavior because, she asserts, only imitation serves as a direct copying process, and if memetics is to be founded on replication events, then only imitation can be counted as a memetic mechanism. But as we have just seen, the jury is still out on whether imitation is behavior copying or mental state inferencing (as assumed in the "theory of mind" literature). This leaves Blackmore's contention somewhat up in the air.

Because of the general discontent with imitation (due to its problematic psychological status), a satisfactory resolution of these interlocking issues was not achieved. However, it was generally felt that all social learning, rather than imitation alone, is a better psychological foundation for the cultural evolutionary process. The famous example of milk bottle-top opening by birds was presented as evidence. The pecking of bottle-tops has now gone on for many bird-generations, and spread through several European countries. Since it is generally felt that birds learn this bit of cleverness not by observing others, but by seeing opened bottle-tops, which inspires their own creativity (a process psychologists call "stimulus enhancement"), it seemed a pity to exclude such an example from the purview of memetics by limiting it to imitation-based diffusion.

However, if this liberal position on social learning is adopted, many repercussions ensue. For example, the phylogenetic history of memes suddenly becomes considerably longer, with birds and perhaps even more "primitive" creatures being allowed to have meme-based "protocultures." If so, then what distinguishes human culture from non-human culture? In addition, it means that direct contact between hosts is no longer required for memetic transmission, since the source of a meme (such as the tit which pecked a bottle-top) can be absent when a new, naive tit arrives on the doorstep. It is the artifact left behind -- that is, the pecked bottle-top itself -- which serves as the proximate stimulus for transmission of the pecking meme to the new arrival. This implies, in turn, that memetics must account for artifact production, since memes can be associated with these constructions, and not just brains. Such implications were not discussed at the meeting.

A second major point of contention was whether the memetic dynamic can be extended into the brain. Can we call individual learning a selection process just like the social transmission process? This proposal met with some disdain, and Henry Plotkin noted that at least among academic psychologists, this is definitely a minority position. Susan Blackmore argued that whatever is happening inside the head should not be considered part of the memetic process; if it is in fact selectionist, it still should be recognized as an independent replicator system. Others argued that including selection among alternative mental representations was crucial to a successful memetics. Two benefits were seen to result from this move by proponents. First, only through an analysis of mental properties and processes can good models of transmission mechanisms, such as imitation, be understood. Second, by extending the Darwinian process into the brain, the confusion of calling thinking --the manipulation of memes -- "directed," "intentionalist" or "Lamarckian" could be avoided. It was felt that the unpopularity of a selectionist psychology may be largely due to the appearance it gives of there being no room for human agency or decision-making, that all human psychology is merely a random selection process among alternative behavioral choices. Of course, the abandonment of intentionality and free will was hailed as a victory for memetics by the mental selectionists. But no consensus was reached on this issue either.

3. Social Science

From the perspective of this group, memetics is largely a promise at present, with no real results to show for itself. As such, the question is whether it will contribute anything new. It was felt that a quasi-epidemiological approach similar to memetics is already in widespread use in the social sciences. The idea that some cultures are more stable, or produce a higher quality of life because certain ideas spread better than others, has long been around.

What memeticists don't recognize, these critics argue, is that one can have a theory of cultural change which is not memetic because it does not involve social learning or the spread of particulate bits of information. For example, evolutionary psychology explains cultural change simply by invoking variation in what the environment stimulates people to recall. All the information for cultural processes is considered by evolutionary psychologists to be already in place in people's heads; the inheritance of these bits of information is genetic. What remains to be explained is not social transmission dynamics, but recall dynamics: what kinds of responses do different environments cause to arise? Thus, existing explanations of diffusion and spread exist which do not invoke memes.

Memeticists miss this "Big Picture" because they are largely unaware of the comprehensive literature which has accumulated in anthropology on cultural change, or the actual history of earlier views (e.g., the cultural diffusionists of the early twentieth century). This leads them to reinvent old wheels and postulate new terms for rejected ideas. Memeticists do not even recognize that the concept of culture -- the thing which memetics intends to explain -- is itself sufficiently problematic that some social scientists advocate its abandonment. The notion simply covers too complex and varied a set of processes to be useful in their view. (What exactly would replace the concept of culture, or what sub-concepts it should be divided into, is not obvious, however.)

What remains unclear to this group is the central claim of memetics: whether there is a novel replicator-based process underlying the population-level, epidemiological dynamic that is culture change. The primary problem of memetics, therefore, is whether there is a new entity on the horizon in whose interests things can be said to happen (the "meme's eye view"). This would be a new kind of function which a social institution might serve: that of the memes. As such, it would represent a real and novel alternative to group-level functionalism, or the various flavors of structuralist thought current in the social sciences. Unfortunately, this central claim has not yet been proven.

In sum, memetics is seen as simply another case of those from outside the discipline, in this case largely biologists, "having a go at explaining culture," but without taking into account many of the complexities this project is widely recognized by contemporary social scientists to entail. The meme critics are happy with the general notion that cultural change involves the diffusion of some vaguely characterized entity, but not with an explanation couched solely in terms of the selection, variation and inheritance of a particulate replicator.

It was also remarked that there is a problem of circularity in the way memetics is generally conducted. Memeticists only study things which seem likely to follow a memetic process, like

fashions and fads (e.g., the infamous backward baseball cap). The perceived success of such empirical adventures leads memeticists to self-congratulation. But many aspects of culture aren't small, isolatable bits of information or practices that readily diffuse in observable time. Take the example of language, which permeates every aspect of culture. How does memetics expect to explain these more fundamental components of culture?

The word "meme" itself has problems. Its close parallel to "gene" may lead memetics astray, if in fact memes are not the same kind of thing. It also produces a "revulsion factor" among those who would otherwise be friendly to the Darwinian cause. Memetics is perceived from outside as an arrogant usurper, making extreme, unwarranted claims. This only serves to put memetics in the same basket with a related attempt at explaining human social life, sociobiology, which was widely seen as what Dan Dennett calls "greedily reductionist." Sociobiology left no ground for social scientists to stand on, and all the interesting questions were subsumed under a single algorithm: the maximization of biological fitness. This is unpalatable to social scientists not just because of territoriality disputes, but because such a greedy reduction is bound to failure. Can all social processes really be reduced to selection and transmission? The box of concepts available from Darwinism doesn't impress this group. It seems a very small toolkit when so many theoretical alternatives are already available and there is so much complexity to explain. In fact, theory abounds in the social sciences. What is lacking is insight into real social processes. Explaining these seems a goal quite far removed from the concerns of most memeticists, who are laboring much further down the organizational hierarchy, worrying about replicators. An uphill battle against a wide variety of other approaches therefore lies ahead for memetics in the social realm.

4. Final Remarks

Many participants observed that despite the shared belief that an evolutionary approach to culture was necessary, significant barriers to communication remained between those from different disciplines. This perhaps derived from the varying histories these disciplines have with evolutionary approaches. In particular, social anthropology has a long history of such thought, which has generally not proven successful. Indeed, a common refrain among those social anthropologists participating in the meeting was "been there, done that." It was difficult for "believers" in memes to convince these historically mindful and hence reticent social scientists that this time around things might be different. Similarly, it was difficult for the anthropologists to explain exactly what went wrong previously, or specifically how the memetic perspective was likely to go wrong itself, even if given a clear run at explaining culture.

This incommensurability of ethos led to an undercurrent of dissatisfaction on both sides. One side seemed to feel that having to address the concerns of "non-believers" kept progress back, while the opposite side felt that the believers "just weren't getting it." Nevertheless, most agreed that bringing both sides together decreased the likelihood that proponents would engage in unchecked, hubristic claims about having explained culture (along with other conundrums such as consciousness), or that social anthropologists would continue to ignore the memetic alternative. Nevertheless, while I don't think anyone was persuaded to jump from one camp to the other, both sides did go away with a lot to think about, and increased respect for those who disagree with them.

A general disappointment was the lack of discussion about what might be called "applied memetics." More time certainly needs to be devoted in future to thinking of ways to do memetics. This should include discussion of existing empirical studies that don't go under the banner of memetics but which could be interpreted as falling within the general purview of this incipient discipline, as well as the development of methodologies for conducting specifically memetic studies in the future. This is because the ultimate test -- which would preempt theoretical objections -- is whether memetics can produce novel empirical work or insightful interpretations of previous results. Everyone agreed it has not yet done so, but must do so in the near future, given the extensive theoretical work already accomplished and the high level of current interest in the subject. Otherwise, it is likely that memetics will soon be perceived to be a failure. This might be considered unlikely if only because, as one participant remarked, just being able to assemble such an eminent, multidisciplinary group to discuss the topic underlines how these ideas are coming to have real force in contemporary intellectual discourse.

CULTURAL EVOLUTION OF “GUIDING CRITERIA” AND BEHAVIOR IN A POPULATION OF NEURAL NETWORK AGENTS

Abstract

An important form of cultural evolution involves individual learning of behavior by the members of a population of agents and cultural transmission of learned behavior to the following generations. The selection of behaviors generated in the process of individual learning requires some "guiding criteria". As with behavior, guiding criteria can be innate or originate from individual or social learning. Guiding criteria play a fundamental role in cultural evolution because they strongly contribute to determine the behaviors that will enter the pool of cultural traits of the population. This work presents a computational model that investigates the nature and function of some forms of "guiding criteria" in the cultural evolution of a population of agents that learn and adapt to the environment using neural networks. The model focuses on the interplay of individual learning and cultural transmission of behavior and those forms of guiding criteria. The model contributes to clarify the nature and role in culture evolution of the guiding criteria studied. Also, within the assumptions of the model, it shows that the cultural transmission of behavior is more effective than the transmission of the guiding criteria.

Keywords: Multi-agent simulation, neural networks, cultural evolution, cultural transmission, reinforcement learning, imitation, behavior, guiding criteria, values, evaluations.

1. Introduction

This work investigates some phenomena related to cultural evolution. Culture can be defined as the total pattern of behavior (and its products) of a population of agents, embodied in thought, action and artifacts, and dependent upon the capacity for learning and transmitting knowledge to succeeding generations (cf. Cavalli-Sforza and Feldman, 1981, page 3). Boyd and Richerson (1985) have presented some mathematical models that specify some of the forms with which cultural evolution can take place. "Direct bias" implies that the descendants directly test (some of) the cultural traits present in the population, and adopt the best ones. "Indirect bias" implies that the descendants adopt the cultural traits of the most successful individuals, while "frequency bias" implies that the descendants adopt the cultural traits with the highest frequency within the population. Finally "guided variation" implies that the behavior is transmitted by one generation to the other ("cultural transmission") and that the agents in the new generation go through a process of individual learning that modifies the acquired behavior before transmitting it to the next generation. Guided variation leads to the evolutionary emergence of new behaviors in the population ("cultural evolution") in a Lamarckian-like fashion. Guided variation is the only form of cultural evolution investigated in this work. Denaro and Parisi (1996) have studied another

type of process that yields cultural evolution in a Darwinian-like fashion, and is similar to the "indirect bias" mechanism. The individuals of the population are ranked according to their success, and the most successful ones are used by the new generation as "cultural models" to imitate. Baldassarre and Parisi (1999) have compared this process of cultural evolution with guided-variation.

Boyd and Richerson (1985, page 132 and 136) underline the importance of "guiding criteria" in the process of individual learning and cultural evolution. They argue that guiding criteria are things like the "sense of pleasure and pain that allows individuals to select among variants", where these (behavioral) variants are generated in the process of individual learning or observed in other individuals. Guiding criteria play a central role in cultural evolution because by determining which behaviors are kept and which are discarded during individual learning, they strongly affect the cultural traits that enter the population's pool of traits through guided variation (this is the focus of this work). The same guiding criteria are also used for the selection of cultural traits in other forms of cultural evolution, such as direct bias (this is not investigated here).

Despite the importance of guiding criteria, Boyd and Richerson do not give a precise description of their nature and origin. They only say that they "could be inherited genetically or culturally or learned individually". Guiding criteria, as their name hints, are a complex compound concept that will require much investigation to be fully understood. The goal of this paper is (a) to contribute to this investigation by presenting a computational model that, by drawing from the biological models of animal learning, defines the nature of some guiding criteria and (b) to study the role of such guiding criteria in the cultural evolution of behavior.

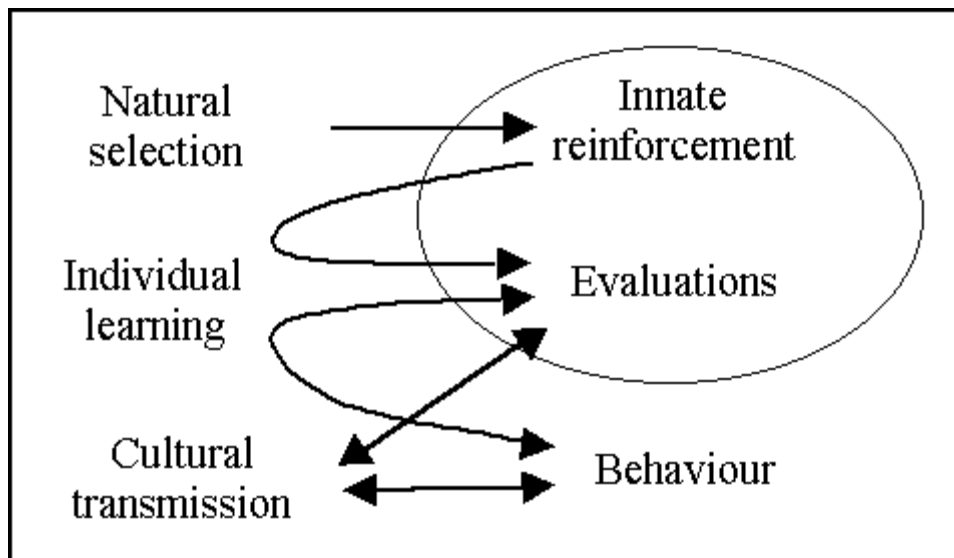

Figure 1: Relationship between the processes and entities investigated in this work. A circle highlights the guiding criteria. Bent arcs indicate relations mediated by individual learning.

The processes studied in this work are summarized in figure 1. The model used in this investigation mimics a population of artificial agents that adapt to the environment by learning to search for "good" food and to avoid "bad" food. This process of learning is based on an innate

capacity to judge the food as good or bad tasting. The capacity to search and avoid food can also be acquired by imitating other agents. Two kinds of guiding criteria are studied in the model. The first is "reinforcement", widely studied in animal learning literature (Lieberman, 1993, for a review). Reinforcement roughly corresponds to an internal neural activation of the agent's brain associated with pleasure or pain. The neural mechanisms underlying this activation are mainly innate (Rolls, 1999). The second kind of guiding criteria are "evaluations" of the perceived state of the world. An evaluation is an internal neural activation of the agent's brain that quantifies the potential of that state to deliver reward in the future. As with the searching and avoiding behavior, the capacity to express correct evaluations can be learned individually or socially from other agents. As we shall see, the capacities to perform correct evaluations and to exhibit adaptive behavior are closely related. The study focuses on the effects that the cultural transmission of evaluations and behavior produces on the level of adaptation of the whole population.

Section two describes the computational models used in the simulations and in particular the neural network controlling the agents and the algorithms mimicking individual learning, imitation, and the transmission of evaluations. Section three presents the results of the simulations and their possible interpretation. Section four describes some related work and, finally, section five draws the conclusions.

2. Methods

2.1 The environment and the task

The environment of the simulations is a square arena with sides measuring 1 unit. Within the arena there are 50 items of white ("good tasting") food, 50 items of black ("bad tasting") food, and a population of 50 agents randomly placed (figure 2). When an agent steps on an item of food, the food is consumed and a new item of the same kind is reintroduced at a random location of the arena. Each agent has a one-dimension "retina" of 5 non-overlapping sensor pairs that receive information from a 180x90 frontal visual field. Each pair contains one sensor sensitive to the color white and one sensitive to the color black. In each cycle of the simulation an agent perceives the environment with its sensors and selects and executes one of three actions: going forward left, going straight, going forward right.

In the simulations, succeeding generations of agents (overlapping in time) live in the environment. Each agent is capable of learning to search for good food and to avoid bad food during its life (individual learning). Also it is capable of learning this capacity from its (only) parent (cultural transmission).

Figure 2: The environment (1x1) with the agents and food items (radius 0.005 and 0.0025 respectively). The "zoom window" shows the 5 visual fields of the 5 white and black pairs of sensors of one agent, and their activation.

2.2 Individual learning

The individual learning process is now described. Figure 3 shows the main components of the learning controller of one agent. The learning controller allows the agents to search for good food and to avoid bad food. The learning algorithms used to train the controller mimic a trial-and-error process and are based on the actor-critic model of Sutton and Barto (1998). See Houk et al. (1995) for a hypothesis of the primate brain's neural structures that correspond to the neural components of the model.

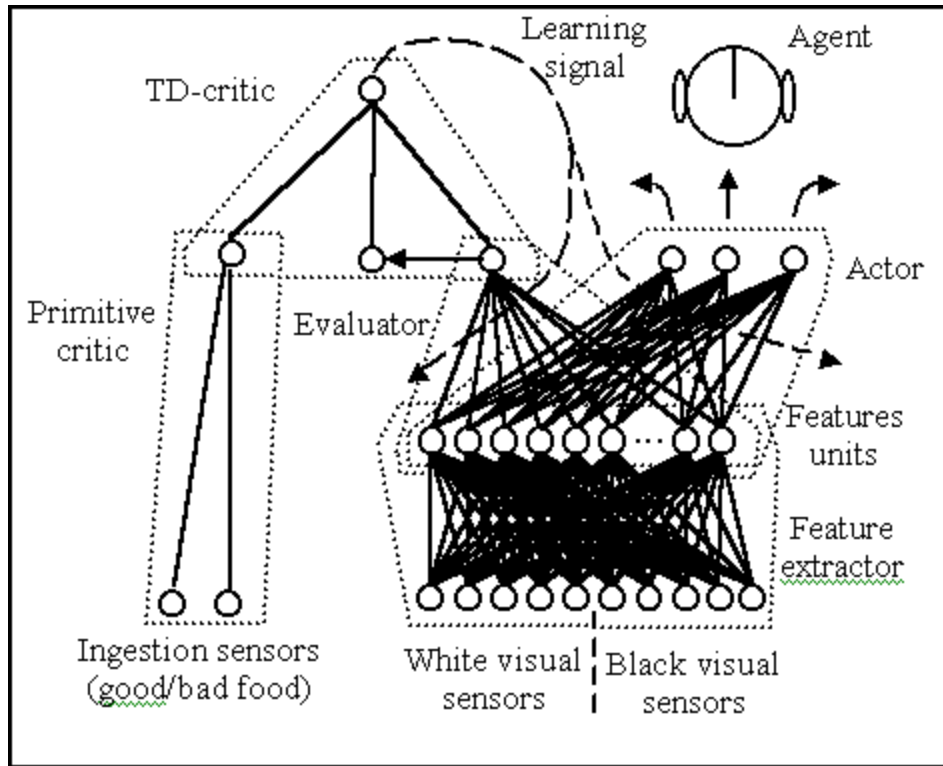

Figure 3: The neural architecture controlling an agent. The circles and arcs represent neurons and connections. The dotted arrows represent the learning signal that allows updating the weights of the evaluator and the actor.

The primitive critic incorporates the guiding criterion of reinforcement considered previously. This guiding criterion is innate. The primitive critic is made up of a simple neural network with two input units (one for the good-tasting food, g , and one for the bad-tasting food, b) and one output unit, r . The input units assume the value of 1 when an item of the corresponding (good or bad) food is ingested and a value of 0 otherwise. The two (innate) connection weights w_g and w_b are set to the value +1 and -1 respectively, so that a reward or punishment ("pleasure" or "pain") is signaled by the linear output unit when an item of good or bad food is ingested. The activation of the output unit is computed as follows:

$$(1) r = w_g g + w_b b$$

The feature extractor takes the 10 signals from the visual sensors as input and implements a "Kanerva re-coding" of them (Sutton and Barto, 1998). The (innate) weights of the feature extractor are randomly drawn from the set $\{0, 1\}$. Each of the feature units (150 in the simulation) activates with 1 if the Hamming distance (standardized to 1 by dividing it by the number of feature units. The Hamming distance between two binary arrays is the number of elements with same position but different values) between the input pattern and the "prototype" encoded by its weights is less than a certain threshold (0.4 in the simulations). If the Hamming distance is greater than the threshold then the feature unit activates with 0. The main function of the feature extractor is to map the input space into a space with a higher dimensionality so to avoid eventual problems of non-linear separability and to attenuate interference problems during learning (Sutton and Barto, 1998).

The actor that is equivalent to the agent's action-selection policy (behavior), is a two-layer feed-forward neural network that takes the activation of the feature units as input and has three sigmoidal output units that locally encode the three actions. To select one action, the activation p_k (interpretable as "action merit") of the three output units is used in a stochastic winner-take-all competition. The probability $P[.]$ that a given action a_g among the a_k actions becomes the winning action a_w is given by:

$$(2) P[a_g = a_w] = p_g / \sum_k p_k$$

The evaluator incorporates the second kind of guiding criteria considered in this work, the "evaluations". An evaluation is a measure of the potential of a state of the world to deliver future reward or punishment. The evaluator is a two-layer feed-forward neural network that gets the activation of the feature units as input. With its linear output unit it learns to express the estimation $V^\pi[s_t]$ of the evaluation $V[s_t]$ of the current state s_t . $V^\pi[s_t]$ is defined as the expected discounted sum of all future reinforcements r , given the current action-selection policy π expressed by the actor:

$$(3) V^\pi[s_t] = E[\gamma^0 r_{t+1} + \gamma^1 r_{t+2} + \gamma^2 r_{t+3} + \dots]$$

where $\gamma \in (0, 1)$ is the discount factor, set to 0.95 in the simulations, and $E[.]$ is the mean operator.

The TD-critic is an implementation in neural terms (weights to be considered as innate) of the computation of the Temporal-Difference error e defined as (Sutton and Barto, 1998):

$$(4) e_t = (r_{t+1} + \gamma V^\pi[s_{t+1}]) - V^\pi[s_t]$$

The evaluator is trained with a Widrow-Hoff algorithm (Widrow and Hoff, 1960) that uses as error the error signal coming from the TD-critic. The weights w_i are updated so that the estimation $V^\pi[s_t]$ expressed at time t by the evaluator, tends to be closer to the target value $(r_{t+1} + \gamma V^\pi[s_{t+1}])$. This target is a more precise evaluation of s_t because it is expressed at time $t+1$ on the basis of the observed r_{t+1} and the new estimation $V^\pi[s_{t+1}]$. The formula of the updating rule is:

$$(5) \Delta w_i = \eta e y_i$$

where η is a learning rate (set to 0.01 in the simulation) and y_i is the activation of the feature unit i . This algorithm implements the individual learning of the evaluations. The idea behind this algorithm can be explained by assuming that the action-selection policy expressed by the actor is fixed. At the beginning of the simulation the weights of the evaluator are set randomly so it will associate evaluations close to 0 to each perceived state of the world (in fact its transfer function is linear). The first time that the agent bumps into a good (or bad) item of food, it perceives a

reward of +1 (or -1), so the TD-critic expresses an error of about +1 (or -1). Given this error, the evaluator learns to associate a higher (or lower) evaluation to the state of the world that preceded the one where the food was ingested. The next time that this state is perceived, it will cause the state preceding it to be evaluated with a higher (or lower) evaluation. This process will continue in a backward fashion so that the agent will finally assign positive (or negative) decreasing (because of the discount factor) evaluations to the sequence of states preceding the ingestion of good (or bad) food.

The actor is also trained according to the error signal coming from the TD-critic, so that the action-selection policy is improved with experience. At the beginning of the simulation the actors' weights are set randomly, so the output units have an activation close to 0.5 for each input pattern (because its transfer function is sigmoid), and the probability of selecting each of the three actions is close to 0.33. This induces the actor to explore the environment randomly. Given that the evaluator (once it has been trained) expresses an evaluation $V^\pi[s_t]$ of s_t according to the average effect of the actions that the actor selects in association with s_t , an error $e_t > 0$ means that the selected action a_w has led to a new state of the world s_{t+1} (evaluated $r_{t+1} + \gamma V^\pi[s_{t+1}]$) that is better than the one previously experienced after s_t . In this case the probability of selecting a_w in association with s_t is increased. Similarly an $e_t < 0$ means that the selected action a_w has led to a state with an evaluation smaller than the average, so its probability is decreased. Formally, the change of the probability is done by updating the weights of the neural unit correspondent to a_w (and only this) as follows:

$$(6) \Delta w_{wi} = \zeta e_t v_i$$

where ζ is a learning rate, set to 0.01 in the simulation.

In the simulation the evaluator and the actor are trained simultaneously. The evaluator learns to evaluate the states of the world on the basis of the action-selection policy currently adopted by the actor, and the actor learns to improve the action-selection policy by increasing the probabilities of those actions that positively surprise the evaluator, i.e. that produce better results than the actions previously selected in the same conditions.

2.3 Cultural transmission

The cultural transmission process is now described. There are two kinds of cultural transmission. Within the first kind, that involves the transmission of behavior, the descendant learns to imitate the behavior of the parent. The descendant should be thought of as following the parent "on its shoulders", perceiving the same visual input, selecting an action (using its actor), observing the action of the parent, and trying to conform its own action to the parent's one. As in Denaro and Parisi (1996), this is implemented by training the descendant's actor network with a Widrow-Hoff algorithm (with learning rate of 0.01). The Widrow-Hoff algorithm uses as output the output signals pk that the descendant associates to the current input pattern and as teaching input the output signals given by the parent. Figure 4 represents this process.

Figure 4: Transmission of evaluations through words and emotions, and transmission of behavior through imitation.

The second type of cultural transmission involves the transmission of "guiding criteria", in this case the evaluations associated by the parent to the states of the world (figure 4). A parent should be thought of as verbally (or emotionally) expressing the evaluation that it associates to the perceived situation and the descendant as learning by listening (or observing). This is implemented by training the descendant's evaluator network with a Widrow-Hoff algorithm (with learning rate 0.01) that uses as output the evaluation that the descendant assigns to the current perceived situation ($V^{\pi}[s_t]$), and as teaching input the parent's evaluation.

3. Results and interpretation

The first simulation is intended to clarify the meaning of "evaluation" used in this work. An agent wanders randomly in the arena (this is done by setting the learning rate of the actor to 0) for 20000 cycles. Its evaluator learns to assign evaluations to each perceived state of the world. A low learning rate of 0.001 has been used to produce stable evaluations. Figure 5 shows the evaluation (averaged across 20 agents) assigned to 10 possible states of the world, each corresponding to the activation of one (and only one) sensor, after 20000 cycles. It can be seen that the evaluation assigned to each state of the world as perceived reflects the probability with which the organism will bump into a good (or bad) item of food. For example, the perception of an item of good food in front (3rd white sensor active) receives the highest evaluation.

Figure 5: Average (over 20 agents) evaluation of 10 different world states, after 20000 cycles of experience.

In order to test the effectiveness of the agents' individual learning process, a simulation where each agent had a very long life (200000 cycles) was run. Figure 6 shows the total number of items of good food, bad food and their difference, collected by the whole population of 50 agents against the number of cycles (the graph plots a moving average over 20000 cycles, and shows the average of three simulations run with different random seeds). This graph and direct observation of agent behavior shows a good capacity to search for good food and avoid bad food.

The following simulations have been run in order to evaluate the effectiveness and role of the different kinds of cultural transmission (introduced in section 2) in the population's cultural evolution. Each agent of the first generation has a life length randomly drawn from the interval $[0, 20000]$. 5000 cycles before its death, each agent generates one descendant to which it transmits some knowledge (vertical transmission, see Cavalli Sforza and Feldman, 1981). Each descendant has a life of 20000 plus a random number of cycles drawn from the interval $[-1000, +1000]$. Each descendant has the same neural structure shown previously and a feature extractor, evaluator and actor with initial random weights. The performance of the population is measured under four different conditions: transmission of both behavior and evaluations; transmission of behavior; transmission of evaluations; and no transmission.

Figure 6: Moving average (20000 cycles) of the items of good food, bad food, and their difference, collected by the whole population.

Figure 7 reports the results of the simulations run under these four conditions (for each condition three simulations with different random seeds were run and averaged). It also reports the plot of figure 6 relative to one organism with a long life. This case can be considered equivalent to a hypothetical situation ("ideal transmission of knowledge") where the cultural transmission from parent to descendant does not include any loss of knowledge due to errors of imitation or communication. In the simulations these errors are reproduced by the fact that the Widrow-Hoff algorithm never brings the error to 0.

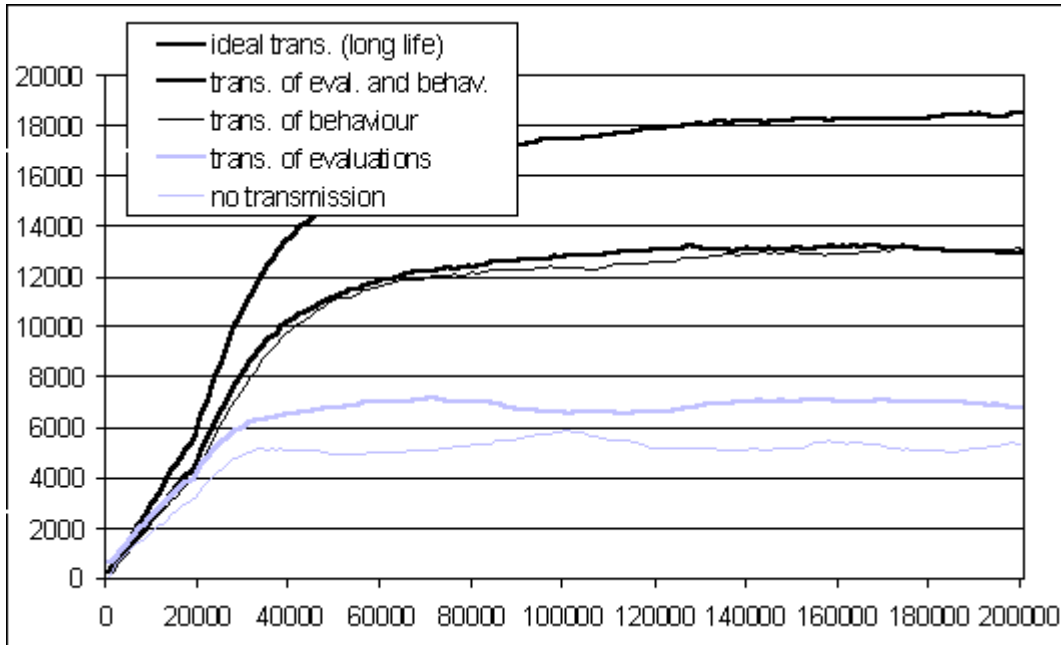

Figure 7: Amount of good food minus bad food collected by the population in the last 20000 cycles.

Three relevant facts are identified through these simulations. The first is that all the three conditions with cultural transmission (transmission of both behavior and evaluations, transmission of behavior, and transmission of evaluations) yield a better performance of the whole population (about 13000, 13000, and 7000 respectively) than the condition where only individual learning is present (about 5000). This means that there is an accumulation of knowledge within the population across the generations: cultural evolution is taking place.

The second interesting fact is that even the most favorable cultural transmission condition (where both behavior and evaluations are transmitted), leads to a performance (13000) inferior to the ideal condition (where there is no loss of cultural knowledge, 18000). This means that the very process of transmission implies a continuous loss of knowledge that prevents the population from reaching the maximum performance. As mentioned, this is due to the fact that the Widrow-Hoff rule never reduces the error to 0. It is also due to the fact that the period of cultural transmission for each agent is limited in time. A further simulation has shown that the shorter the cultural training period for each agent, the lower the population performance level reached in the long term (see figure 8, averaged for three random seeds). This result is attenuated by the fact that in the simulations cultural transmission has (unrealistically) no costs.

Figure 8: Performance of the population when the cultural transmission period for each agent is 5000 versus 3000 cycles.

In order to test the interpretation of the first and second facts, another simulation was run with the three distinct cultural-transmission conditions, but with a "synchronized" population: each agent has a life lasting precisely 20000 cycles, first generation included. To reveal changes at a finer time granularity, the performance of the population (determined by the difference between the number of good and bad food items collected), has been measured with a moving average of 1000 cycles (versus 20000 cycles used in the previous simulations; to keep the scale consistency the performance has been multiplied by 20). The results are shown in figure 9 (averaged for 3 random seeds). For clarity the plot relative to the condition with both transmissions of behavior and evaluations is not reported in the graph because it closely resembles the condition with the transmission of behavior only.

It can be noted that in both conditions (but in particular with the transmission of behavior) each new generation, with the exception of the first one, starts its life with skills above the "ignorance" level (i.e. 0). This explains the population's improving performance shown in figure 7, and shows the nature of the cultural evolution process: each newly born agent enters the adult life already possessing some skills. During its life it further improves these skills, and then passes the refined skills to its descendent. The result is an increase of the population average performance across generations.

It can also be seen from figure 9 that at each passage from one generation to another the performance decays abruptly. This is due to the errors of transmission of behavior and evaluations mentioned before.

Figure 9: Performance of the population when the generations are synchronized.

The third relevant fact that emerges from the simulation reported in figure 7, quite unexpected, is that cultural transmission of behavior is greatly superior to cultural transmission of evaluations (13000 against 7000).

Figure 10: Evaluation assigned to an item of good food perceived with the central sensor. Average for the population.

Figure 10 explains this finding by showing the dynamics of the evaluations of the first and second generations (20000+20000 cycles) of the preceding simulation. Every 1000 cycles the evaluation that each agent has assigned to the last item of good food seen with the white central sensor (all the other sensors being off) is measured and an average is computed for the population. This evaluation can be considered as an indicator of the overall capacity to evaluate.

In fact good food in a frontal position is highly promising of reward and deserves a high positive evaluation. So an agent that has learned to evaluate correctly the states of the world should express a high evaluation in this circumstance.

The most surprising fact is that the second generation's capacity to give correct evaluations at the beginning of life (cycle 21000), is higher with the transmission of behavior than with the transmission of evaluations (0.5 versus 0.4). The possible explanation of this fact is that once the descendants have culturally inherited the behavior that leads to search for good food and avoid bad food, they rapidly learn the evaluations by individual experience. The graph shows that after 7000 cycles (cycle 27000) the descendants have already learned to express evaluations similar to the parents' ones, and even improve on their parent's evaluations. At the level of population's performance this fact renders cultural transmission of behavior quite effective, as shown in the previous simulations.

Where the descendants inherit the evaluations, they are not capable of directly using them to search for good food and avoid bad food, because they do not possess the behavior necessary to do so. The immediate consequence is that the evaluations are themselves corrupted (from cycle 20000 to cycle 25000) because they prove to be incorrect: after all, having good food in front of you is not a very promising situation if you are not capable of reaching for it! The long-term consequence is that the descendants recover evaluations similar to the parents' ones only after 16000 cycles (cycle 36000), near the end of their life. At the level of population this causes a severe loss of skills passing from one generation to the other, and this makes the process of cultural transmission of evaluations quite ineffective, as shown in the previous simulations.

4. Related work

Several computational models of imitation and social transmission of skills and knowledge have been developed. Here those that use reinforcement learning, and that are closely related to the model presented in this paper, are reviewed.

Lin (1992) presents a model (tested within a food-gatherer predator grid world) where a reinforcement learning agent learns from its own recent past experience ("experience replay") by being (re-) exposed to histories of quadruples of the type "state-action-next state-reward" suitably stored in a buffer. This increases the speed of learning. This model is relevant for social learning because the "experience" could potentially derive from another agent. Tan (1993) presents a model (tested within scout-hunter/co-operative hunters grid worlds) where reinforcement learning agents communicate perceptions or use and update the same policy, so obtaining advantages in terms of speed of learning and performance. Clouse (1996) presents a model (tested using the Race Track game) where a reinforcement learning agent can execute an action "suggested" by an expert teacher instead of its own action. It is shown that higher rates of learning are obtained with high probabilities of suggestion per step. Finally Price and Boutillier (1999) present a model (tested with grid-maze tasks) of "implicit imitation". Here a reinforcement learning agent observes the effects produced by actions executed by a mentor, uses them to build a model of the world (state transitions induced by the mentor's actions), and then trains itself to act by using this model (model-based reinforcement learning).

All these models use a form of "greedy policy" to select actions. This implies that the action to be executed is directly selected as the one with the highest expected (cumulated discounted) future reward. No merits or probabilities are explicitly stored for the selection of actions. In contrast, this storage takes place in the actor-critic model adopted in this paper, and appears to happen in real organisms (Houk et al., 1995). In the research presented here it has been the adoption of a model which includes explicitly stored merits that has allowed separation of the modification of the evaluations from the modification of behavior, and the investigation of their relationship.

5. Conclusion and future work

An important form of cultural evolution involves the social transmission of behaviors and skills from one generation to the next, and a change and eventually improvement of these by means of individual learning and experience. The change of behavior and skills by individual learning requires some "guiding criteria" to be accomplished, which determine which new behaviors and skills will be selected and retained, and which will be discarded. In the long term, the guiding criteria strongly bias which behaviors and skills enter the pool of cultural traits of the population, and as such they play a central role in determining the cultural evolution of a population. This work is intended to contribute to the clarification of the nature of "guiding criteria". With this purpose it focused on some guiding criteria with a well-established biological origin: the reinforcement, that is mainly innate, and the evaluations, that are learned with experience or themselves culturally transmitted. After presenting a computational model incorporating these concepts, the different effects produced by the transmission of behavior and evaluations on one aspect of the adaptation of the population have been investigated. First, the simulations have helped to clarify the nature of the form of cultural evolution considered here, and have shown that the cultural transmission of evaluations and behavior produces positive effects on the performance of the population. Second, they have shown that cultural transmission is more effective if the loss of knowledge and skills due to errors of imitation and communication is attenuated by longer training of new generations. Third, and most importantly, they have shown that the transmission of behavior is more effective than the transmission of evaluations. It should be noted that this result holds within the assumptions of the model (where evaluations are changed quickly if shown to be inconsistent with direct experience). However, it could be the case that culturally learned evaluations persist in the face of contrary direct experience in real agents (this could eventually be modeled with different reinforcement learning algorithms). The final answer can only come from an empirical validation of the prediction of the model here presented.

This work has considered only a few forms of guiding criteria, namely reinforcement and the evaluations originating from reinforcement. These have a biological origin, and have been generated (or the mechanisms that generates them has been generated) by natural selection because they enhance organisms' fitness. Other forms of guiding criteria probably have an origin more strongly related to cultural processes and may eventually counter-act biologically generated criteria. For example, Miceli and Castelfranchi (1999) have investigated a notion of evaluation different from that considered here, related to the cognitive formulation of goals, and the notion of "values" (a special kind of evaluation where the goal is left unspecified). These other kinds of

guiding criteria, and their relation with the biological ones, should be the object of investigation in future work.

ASSERTION 1

The human being, characterized by a remarkable ability to process information...

In the first sub-clause of the opening sentence, the human ability to communicate complex thoughts to each other is elevated above all other aspects of our existence.

Although expressed in computer jargon, this separation of thinking from doing is one of the oldest inversions found in philosophy, as in Plato's parable of the cave. For centuries, it was used the conjuring trick of the priestly caste - elevating the speaking of sacred words above physical toil on the earth of the peasants. After over two centuries of modernity, it is surprising to find this ancient idea at the beginning of a declaration supposedly describing the future. But, as we will see, the process of seeing the world upside down is one of the most important failings of the whole Memesis statement.

ASSERTION 2

Let's start again:

The human being, characterized by a remarkable ability to process information, has extended his phenotype further than any other species. Complex tools and technologies are an integral part of our evolutionary "fitness". Human evolution is fundamentally intertwined with technological development; the two cannot be considered apart from one another. Humanity has co-evolved with its artifacts; genes that are not able to cope with this reality will not survive the next millennium.

The other major error in the Memesis statement is its use of dodgy biological analogies. The discovery of evolution was one of the key intellectual moments in the development of modern society. By offering a rational understanding of the origins of humanity in nature, it destroyed the intellectual basis of revealed religion. Crucially, evolutionary theory was conceived in the first truly modern society: Great Britain. The rapid economic and social changes taking place in this first industrial society enabled Darwin to understand that nature itself was also in flux.

However, problems arise when the relationship is drawn in the other direction: when natural evolution is used to explain social development. In this century, millions of people were shoved into gas chambers because it was believed that they possessed 'genes that are not able to cope' as the Memesis statement puts it. Following the defeat of fascism, the biological metaphor is now more often used to revive an earlier illegitimate use of Darwinian Theory for political purposes: Social Darwinism. As championed by Herbert Spencer, this theory claimed that unregulated market competition between private property owners was a natural phenomenon rather than a social one. The moral claims of liberalism were restated in positivist language. For instance,

Spencer even opposed the installation of municipal sewerage systems to prevent cholera and other diseases as an obstruction of the natural laws of the market!

Although discredited in the early part of this century, the globalization of capitalism over the past few decades has been accompanied by a renewed faith in the simplicities of liberal economics. In turn, the idiocies of Spencer have been revived in an updated form - as can be seen in Kevin Kelly's book 'Out of Control'. By adopting the rhetoric of biology, the Memesis statement is not simply trying to reduce the complexities of millennia of social development to the self-replication of DNA proteins. It is also implicitly supporting the failed social and economic policies of the 1980s.

ASSERTION 3

As an analogy to the building blocks of biology, the genes, memes describe cultural units of information, cognitive behavioral patterns that propagate and replicate themselves through communication. From the "bio-adapter" of language as a proto-meme to the "infosphere" of global networks as the ultimate habitat for the human mind.

If you combine two errors, you go further into confusion. Having separated thinking from doing and reduced society to biology, the Memesis statement now goes on to assert that human consciousness is an autonomous gene! Dressed up in newly fashionable biospeak, what we have here is a garbled fusion of:

- The old Stalinist lie that history is a process without a subject;
- The old post-structuralist lie that language speaks us;
- And the old McLuhanite lie that technology shapes our minds.

For if memes 'replicate themselves', what are humans doing in the meantime? We're not the blind objects of genes or memes. Rather, whether using language or global networks, humans transform themselves and nature through our own activity. We are the subject of history - even if it is not always in circumstances of our own choosing.

ASSERTION 4

The discussion is intended to probe specific segments of the techno-cultural revolution against the background of the idea of a "culturally based history of creation".

So now we get to the core of the Memesis statement. The current process of the convergence of telecommunications, the media and computing is to be explained through the dubious biological metaphor. The prosaic task of developing the hardware and software for an integrated communications and information network is to be transformed into a positivist mysticism: the fulfillment of our pre-programmed genetic destiny. Henri Lefebvre remarked that structuralism, semiotics and psychoanalysis were usually used by intellectuals as ways of avoiding examining the social relations of capitalism. Now we can add biology to the list.

ASSERTION 5

...and also science fiction!

This is not to develop new utopias, but rather to critically assess the current scenario, which promises the fulfillment of long prophesied visions of the future. The possibility of the emergence of a post-biological, cyberorganic line of evolution out of universal binary code systems, of which the first protozoans have names like Internet, Cyberspace and I-way.

The Memesis statement is certainly not advocating a 'new utopia'. It is instead repeating one of the oldest plots in science fiction: the Frankenstein monster, Hal in 2001, the Terminator and so on. But, whereas in the past we were supposed to fear the destructive powers of technology, we're now invited to celebrate 'the emergence of a post-biological, cyberorganic line of evolution'. The ending might be more optimistic, but we've read the book and seen the film before.

And where is this new life form supposed to come from? Allegedly it emerges from the 'Internet, Cyberspace and I-way'. Yet the Net is a creation of human labor. Someone has to dig holes in the road to lay the fiber-optic wires. Someone has to work on the production line building the PCs. Someone has to design the hardware which will control the flow of data across the networks. Someone has to write the software to enable people to use the Net. And all of us participate in communicating across cyberspace with one other. Without human activity, the Net is nothing but an inert mass of metal, plastic and sand. We are the only living beings in cyberspace.

ASSERTION 6

As the biological body coincides with its mechanical and now informational clone as well, neurobionic, robotic prosthetics question our relationship to the body and to gender; cyborg theory and cyberbody fetish as response.

If the Net can be explained by Social Darwinism, why not recent advances in medical science also? In an orgy of hyperbole, people with pacemakers - or even glasses - can become characters from science fiction tales: the cyborgs. Deprived of the consolation of religion, we can now rediscover the promise of eternal life in a new hi-tech form.

But by embracing this positivist mysticism, we ignore the creative powers of our own species to transform its own conditions of existence. Above all, it is not technology by itself which has changed our perception of gender relations. Rather the possibilities of modernity have been grasped by women – and some men - to transform the limitations on human existence imposed by patriarchal societies and biological necessity. It might seem deliciously wicked to indulge in 'cyborg fetish', but worshiping the machine and the gene obscures past and present struggles of flesh 'n' blood humans to civilize social relationships between the genders.

ASSERTION 7

Media memory - the collective memory and experience of humanity externalized in world-wide networks. Memes, as a "mass crystal", the identification and integration of virtual communities that gather only in network interfaces. After repeatedly claiming that memes are self-replicating, the Memesis statement suddenly announces that 'media memory [is] the collective memory and experience of humanity externalized in world-wide networks'. So the memes are actually our own creation. But, if there is active human involvement in the construction of cyberspace, how can technology and genes be autonomous forces outside our control? The fetishistic conception of technology and information within the Memesis statement is now openly revealed for the first time. What we're dealing with here is a moment of Feurbachian revelation: the Memesis statement now admits that it wants us to worship the magical power of graven images built with our own labor.

The central error of the Memesis statement has become obvious. It regards machines and information as autonomous things outside our control. Yet, in reality, both technology and culture are expressions of the social relationships between individual humans. It is human activity which is crystallized into machines and information, not memes which create 'mass crystal'. Crucially, by denying the Promethean power of collective creativity, the Memesis statement ignores one of the central questions of modernity: how are the rewards of labor to be divided among the different groups involved in the social production of machines and information? Ah, but the social question is so unfashionable nowadays...

ASSERTION 8

Memes, the cognitive pixels as a blueprint for the cultural practice of sampling, of the universal "copy and paste", which has emerged from the new conditions of media.

Having briefly admitted that humans are the subject and culture is the object of their labor, the Memesis statement quickly reverts to its favorite philosophical inversion dressed up in computer jargon. Once again, it is not clever artists, musicians or designers who use digital technologies to create innovative new forms of cultural expression. On the contrary, the software mystically writes itself!

Moreover, the practice of sampling the work of others is hardly new. For centuries, artists have plagiarized their predecessors and contemporaries. All collective endeavors involves a constant process of sampling and 'copy and paste'. What the new information technologies have done is make the process much easier and more aesthetically pleasing.

Above all, they have enhanced and deepened the possibilities of strange juxtapositions and hallucinatory combinations. The Futurists could only dream of machine music. Jungle musicians can now actually create the digital rhythms of drum 'n' bass.

ASSERTION 9

Memesis: a synonym for the current process of compression, for the convergence of various developmental vectors, which achieve a breakthrough as a whole.

Exhausted, we at last reach the end of this journey through intellectual confusion. Assuring that this was all just a 'synonym' for the process of convergence, the statement concludes with the promise of imminent rapture: 'a breakthrough as a whole'. But, at best, the Memesis statement is a piece of bad poetry. At worst, it is an apology for the defunct neo-liberalism and tired post-modernism of the last decade. The Memesis statement presents a 'Californian Ideology' for Europeans: radical rhetoric hiding conservative ideas.

The real crime of the Memesis statement is the way that it willfully obscures the process of human innovation and creativity under a mass of dodgy biological metaphors. In contrast, we must celebrate the Promethean power of humans to create - and recreate -themselves. It is precisely our refusal to accept our biological destiny which makes us more than insects. Unlike our fellow species, we can transform ourselves through thought and action.

The advent of modernity has radically accelerated this process of human self- transformation. The 'convergence of various developmental vectors' - as the Memesis statement so inelegantly puts it - is only the latest stage in this process of modernization.

What is interesting about our present situation is how imaginative people are using new technologies to push forward the limits of social and cultural creativity. Instead of being mesmerized by memes, what we should be doing instead is celebrating the achievement of these digital artisans - the artist- engineers who're pioneering the ways in which everyone will be able to participate within cyberspace in the future.

MEMETIC MEANINGS A COMMENTARY ON ROSE'S PAPER: CONTROVERSIES IN MEME THEORY

By

Francis A. Beer

beer@spot.colorado.edu

Tel. +1 303-492-7802

Rose (1998) raises a number of important issues for the developing area of memetics. These include the ambiguous definition of central terms like 'meme', memetics' use of central analogies and metaphors from genetics, and the role of philosophical concepts like 'self' and 'mind' in memetics. All these can be considered as issues of meaning.

1. Definitions and Meanings

"The definition of a meme," Rose begins, "is currently ambiguous.... Without some kind of firm definition the word 'meme' becomes almost meaningless."

The set of problems centering on definition and meaning is serious but hardly limited to memetics. The empirical study of semantics tells us that various modifiers in different contexts subtly transform the definitions and meanings of most words. As our language becomes more distant from direct physical experience of the physical world, it builds upon itself to create and use abstract, general concepts. The core meanings, the constants diminish; contextual parameters gain heavier weight.

This semantic indeterminacy is true for words such as 'reason', 'validity', and democracy for example (Beer, 1997; Beer, 1994 ; Speel, 1997). It is not surprising, and should not be that the word 'meme' is similarly multivalent. The general nature of semantics leads us to expect no less.

2. Analogies and Metaphors

Rose provides a number of alternative definitions of 'meme' together with current sources. Yet memetic genealogy is much longer than even his capable review suggests (Best, 1998). The field of rhetoric, for example, has long included the classical term 'enthymeme' which dates from classical times. In contemporary usage, the biological term 'gene' is a central current orienting analogue or metaphor for 'meme'. Genetics thus provides a primary, foundational orientation for memetics.

The field of cognitive linguistics suggests that there are two ways in which this genetic metaphor may work. We may call one of these, the strong program. In this program, memes are considered as nominal categories. Further, there is a direct mapping of attributes from the genetic source to the memetic target. (Lakoff, 1994). In this situation, we should expect all genetic characteristics

to be faithfully mapped into memetic space. All genetic attributes, however, do not faithfully reproduce in memetic space. Much of Rose's article, as well as other work, focuses on such general mapping anomalies from genetics to memetics, as well as differences in memetic applications in different fields (Beer, 1997). The strong program carries within it the seeds of its own disappointments. Memes may be like genes in certain ways, but they cannot be identical if only because of the differences between physical and cultural phenomena.

We may call another model of metaphorical process the weak program. In this program, memes are considered as interval categories, values for which may be derived through statistical regression or factor-analytic techniques. It implies a more subtle, complex, and non-linear dynamic of metaphorical meaning construction. This model is more forgiving since it allows genes to provide a general orientation for the meaning of memes, but does not place memes into a conceptual straight jacket. Instead of fitting memes to genes, it blends them. Further, the meanings of memes and memetics might take part of their inspiration from genetics, but there would be other sources and associations. The fit would be looser. Memetic meanings would be freer to adapt and evolve independently from their origins, depending on their uses and contexts. (LSA; Rohrer, 1997; Turner and Fauconnier, 1995).

3. Selves

This brings us to thorny philosophical problems of the self and others, free will and determinism. These terms have developed specific meanings within the context of genetic theory. For example, while genetics has accepted the identity of the organism, it has also partly relocated selfhood to the genetic level, the level of the 'selfish gene'. This genetic self is similar to the individual organism self in many respects, but it differs in several important ways. First, the genetic self is prior to and determinative of the individual self. Second, the genetic self acts randomly and blindly - not consciously and intentionally with goals and foresight.

Memetics moves forward from this position by posing new questions about the self. It asks us to consider the possibility that individuals or cultures may develop selves with both genetic and memetic cognitive capabilities for foresight and prediction, intentionality and goal specification, planning and structured action. This appears to involve a reorientation of the basic genetic model of the self, yet there need be nothing particularly shocking about this evolutionary memetic adaptation. In the first place, as we suggested earlier, memetics need not directly mimic genetics. Indeed, memetics may suggest new directions for genetic theory. Second, such conscious capabilities may be easily integrated into the basic evolutionary framework. Genetic foundations exist for such attributes. Evolutionary psychology, moreover, suggests that normal mechanisms of cellular growth, memory and learning may explain memetic learning.

Are memetic capabilities helpful to survival? Evidence suggests that they probably are. The Darwinian theory of evolution was itself a memetic adaptation. Though it is not often noted, Darwinian theory suggested that human beings were not blind, that the evolutionary theorist, at least, could perceive with some accuracy the structures and processes of nature. Darwinism contains within itself both memetic and genetic models for the self - memes for scientists, genes for nature. Darwinism implied that scientists, armed with proper knowledge, could predict future

natural events. Scientists could, further, plan and act intentionally to collect and interpret natural data.

4. Minds

Memetics advances from these origins along multiple parallel fronts. One of these is in the area of "mind." As we have suggested, it seems reasonable that minds include cognitive tools for representation, foresight, choice, and action and that these are genetically, biologically based, culturally and socially developed and programmed. These capabilities interact with other biological systems through complex feedback mechanisms and influence organisms' survival capabilities in different environments.

At the same time, we must recognize that the meaning of `mind', like `meme', is multivalent and metaphorical. `Mind' has different meanings in biological, psychological, linguistic, and philosophical contexts.

To pose the problem as free will versus determinism may obfuscate the complexity of the situation. Free will or determinism may simply exist as different interpretations of the same phenomena in different theoretical contexts. From the naïve perspective of everyday common sense, free will begins at the body's edge. Philosophically and legally, free will is the essential component of our individuality, of our dignity, of our rights and responsibilities. From a biological or medical perspective, free will may represent the effects of unknown variables within deterministic systems; indeterminable interactive effects of multiple known variables within complex systems; or random error of otherwise deterministic processes.

As memetics develops, it will generate new meanings both for itself and for associated concepts and terms. Old analogies and metaphors, for example genetics and genes, may diminish in importance. New ones, perhaps centering on patterns of information, will gain. In any case, memetics will help reshape how we think about ourselves and our minds. For the time being, free will and determinism uneasily coexist. The emerging discipline of memetics will help us track their meanings as they evolve.

MODELS FOR INTERACTING POPULATIONS OF MEMES: COMPETITION AND NICHE BEHAVIOR

By

Michael L. Best

Media Laboratory,
Massachusetts Institute of Technology,
Cambridge, Massachusetts 02139, USA.
mikeb@media.mit.edu

The original version of this paper was published as Best, M.L. (1997). Models for Interacting Populations of Memes: Competition and Niche Behavior. In Husbands, P. and Harvey, I. (eds.) (1997). *Fourth European Conference on Artificial Life*, Cambridge, MA: MIT Press. MIT Press has kindly given us permission to re-publish this new version.

Abstract

We make use of a set of text analysis tools, primarily based on Latent Semantic Indexing, to study the dynamics of memes on the Net. Our analysis discovers replicating memes within posts to the USENET News (or NetNews) system. We cluster the posts to NetNews into clouds within a conceptual sequence space; these clusters describe quasi-species. We then go on to study the pairwise interactions between these quasi-species by computing the cross-correlation between the interacting population's level of post activity. We analyze a particular corpus of posts to the soc.women newsgroup and argue that strong negative cross-correlations are examples of competition between the quasi-species. We find that high levels of competition occur more frequently among quasi-species who exist within a narrow ecological niche. We note that this phenomena also occurs in natural ecologies.

1 Introduction

Ideas do not exist in a vacuum. Neither does discourse, the interconnected ideas which make up conversation and texts. In this research we investigate the pairwise interaction between populations of ideas within discourse: Are our text populations in competition with each other? Do they mutually benefit each other? Do they prey on one another?

This work attempts to build models of *population memetics* by bringing together two disciplines: Alife and text analysis. Through techniques of text analysis we determine the salient co-occurring word sets, texts, and text clusters, and track their temporal dynamics. We then study the life-like properties of this human-made system by considering its behavior in terms of replicators, organisms, and species.

Richard Dawkins coined the term *meme* to describe replicating conceptual units (Dawkins [7]). In studying the population dynamics of ideas we consider the meme to be the largest reliably replicating unit within our text corpus (Pocklington & Best [27], Pocklington [26]). Through text analysis we identify memes within a corpus and cluster together those texts which make use of a common set of memes. These clusters describe species-like relationships among the texts.

The particular texts we study are posts to the popular USENET News (or NetNews) system. These posts form the basis of a new Alife environment, the *corporal ecology* (Best [4, 5]). In this ecology texts are the organisms, the digital system defined by NetNews describes an environment, and human authors operating within some culturally defined parameters are the scarce resource.

At the core of our study sits a large text analysis software system based primarily on Latent Semantic Indexing (LSI) (Furnas, et.al [16], Deerwester, et.al. [9]; Dumais [10, 11]). This system reads each post and computes the frequency with which each word appears. These word counts are then used in computing a vector representation for each text. A principal component analysis is performed on this collection of vectors to discover re-occurring word sets; these are our memes. Each post is then re-represented in terms of these memes. By grouping texts which are close to one another within this meme-space we cluster semantically similar texts into species-like categories or *quasi-species* (Eigen et.al. [12]).

We proceed to study the interactions between those populations which coincide temporally. For each cluster we compute a series which represents its volume of post activity over time, for instance how many texts of a given cluster were posted on a given day. Cross-correlations between each pair of time series are then determined. We find that some pairs have strong negative correlations and argue that these are examples of texts in competition. A number of examples of such competition are explored in depth. We argue that high competition is correlated with those text clusters which exist within a narrow ecological niche; this phenomena is also observed in natural ecologies (Pianka [24]).

Note that this is an unusual shift from the typical Alife environment. We are not synthesizing replicators, embodying them into agents, and observing their life-like interactions. Instead we are studying a pre-existing artifact. Through our analysis we *discover* replicators within organisms, and use computational techniques to observe their dynamics.

In this paper we first briefly overview the NetNews environment and describe the LSI based text analysis system. Next we describe the mechanism used to determine the temporal dynamics and cross-correlations given a corpus of posts. We then relate the cross-correlations to models of interacting populations. In the next section we examine in depth a couple pairs of post clusters with strong interactions. We then describe a theory of niches within the corporal ecology and note that narrow ecological niches are correlated with significant competition. We end with our conclusions.

2 The NetNews Corpus

Understanding our corpus requires a basic knowledge of the NetNews system. NetNews is an electronic discussion system developed for and supported on the Internet (Kantor & Lapsley [18]). Discussion groups have formed along subjects ranging from science to politics to literature to various hobbies. The collections of messages are organized into particular subject groups called *newsgroups*. The newsgroups themselves are organized in a tree-like hierarchy which has general top-level categories at the root and moves to more specific topics as you progress

towards the leaves. A newsgroup name is defined as the entire path from the top-level category through any subsequent refining categories down to the name of the group itself. Category and group names are delimited by the period symbol. Thus, ``soc.religion" is the name of a newsgroup concerned with social issues around the world's religions and ``soc.religion.hindu" is a more specific group devoted to Hinduism.

Texts sent to NetNews, the *posts*, are composed of a number of fields only a few of which are relevant here. The user creating the post is responsible for the post body (that is, the actual text of the message) as well as a subject line. The subject line is composed of a few words which describe what the post is about. NetNews software will attach a number of additional fields to posted messages including a timestamp and the user name of the person who created the post.

Posts can be either an independent message or a follow-up to a previous message. A follow-up, or ``in-reply-to" message, will have special threading information in its header linking it to the previous posts to which it is a reply. This header information allows news readers to reconstruct the discussion thread.

NetNews today has grown considerably from its beginnings in the late 70's and 80's. With over 80,000 posts arriving each day, it provides an excellent dataset for the study of cultural microevolution.

3 The Text Analysis Method

We analyze a corpus of posts to NetNews to distill their salient replicating unit or memes, and to cluster together posts which make common use of those memes. We do this by employing a large system of text analysis software we have built. The techniques employed are based on the vector space model of text retrieval and Latent Semantic Indexing (LSI).

3.1 Vector Space Representation

We begin with a corpus composed of the full-text of a group of posts. We analyze the corpus and identify a high-dimensional space which describes the conceptual elements within the texts. For each post we identify a point within this space which captures it semantically. This technique is known as a vector space representation (Salton & Buckley [28]; Frakes & Baeza-Yates [15]). Each dimension in this space will represent a *term* from the corpus where a term is a word that occurs with some frequency (e.g. in at least three posts) but not too frequently (e.g. the word

``not" is dropped from the term list). The goal is to arrive at a set of terms which semantically capture the texts within the corpus.

Given the conceptual space described by this set of terms each post can be represented as a point within this space. We score each document according to the frequency each term occurs within its text, and assign each term/document pairing this *term weight*. The weighting we use for each term/document pair is a function of the *term frequency* (simply the number of times the term occurs in the post) and the *inverse document frequency* (IDF). Consider a corpus of m posts and a particular term, j , within a list of n terms. Then the IDF is given by,

$$IDF_j = \log(\text{floor}(m - m_j) / m_j)$$

where m_j is the number of posts across the entire corpus in which term j appears. Thus, if a term occurs in 50% or more of the texts the IDF for that term will vanish to zero. But if, for instance, a term occurs in 10% of the documents the IDF will be $\log(10)$. In words, rare terms have a large IDF.

The term weight for a document, i , and term, j , is then defined by,

$$TermWeight_{ij} = w_{ij} = \log(TermFrequency_{ij}) \cdot IDF_j.$$

Each term weight, then, is a function of the inter- and intra-document term frequencies. Each post, i , is now represented by a particular term vector, $r_i = (w_{i1}, w_{i2}, \dots, w_{in})$. The entire collection of m term vectors, one for each post, define the *term/document matrix*, A .

This set of steps, culminating in the term/document matrix, form the basis for much of modern text retrieval or filtering and are at the core of most Web search engines.

3.2 Latent Semantic Indexing

LSI is a technique used to distill high-order structures from a term/document matrix, consisting of sets of terms which re-occur together through the corpus with appreciable frequency. The re-occurring term sets are discovered through a principal component method called Singular Value Decomposition (SVD). While LSI was primarily developed to improve text retrieval, we are interested in its ability to find replicating term sets which act as memes. We will first overview the LSI technique and then discuss how it discovers memes.

LSI was originally proposed and has been extensively studied by Susan Dumais of Bell Communications Research and her colleagues (Furnas, et.al. [16]; Deerwester, et.al. [9]; Dumais [10, 11]). Peter Foltz investigated the use of LSI in clustering NetNews articles for information filtering (Foltz [14]). Michael Berry and co-authors researched a variety of numerical approaches to efficiently perform SVD on large sparse matrices such as those found in text retrieval (Berry [1]; Berry, et.al. [2]; Berry & Fierro [3]).

The SVD technique decomposes the term/document matrix into a left and right orthonormal matrix of eigenvectors and a diagonal matrix of eigenvalues. The decomposition is formalized as, $A_k = U V^T$.

The term/document matrix, A , is approximated by a rank- k decomposition, A_k ; in fact the SVD technique is known to produce the *best* rank- k approximation to a low-rank matrix (Berry [1]).

We are interested in only the right orthonormal matrix of eigenvectors, V^T . Each row of this matrix defines a set of terms whose co-occurrences have some statistically salient re-occurrences throughout the corpus. That is, each eigenvector describes a subspace of the term vector space for which the terms are frequently found together. These *term-subspaces* describe a set of semantically significant associative patterns in the words of the underlying corpus of documents; we can think of each subspace as a *conceptual index* into the corpus (Furnas et.al. [16]).

For instance, an example term-subspace generated by analyzing a collection of military posts found three words as having significant re-occurrences, and therefore replicating together with success: ``harbor'', ``japan'', and ``pearl''. These term-subspaces make up our replicators and are our putative memes. Memes are not single re-occurring words but are made up of *sets* of re-occurring words.

Our final text analysis step is to ``compress'' the original term/document matrix by multiplying it with this right orthonormal matrix of eigenvectors (in other words we perform a projection). This, in effect, produces a *term-subspace/document* matrix. Each post is represented by a collection of weights where each weight now describes the degree to which a term-subspace is expressed within its post's text.

4 Meme and Quasi-species

4.1 Term-subspace as Putative Meme

We are looking for replicators within the corpus which are subject to natural selection. Elsewhere we have argued at length as to why the term-subspace captures the requirements of a true meme because its word sets act as a unit of selection within the corpus (Best [4, 5]; Pocklington & Best [27]). The strengths of this term-set as a replicating unit of selection are due to it meeting the following conditions:

- it is subject to replication by copying,
- it has strong copying fidelity,
- but not perfect fidelity, it is subject to mutation,
- it has a strong covariance with replicative success

(Lewontin [19]; Eigen [13]).

We will quickly review each of these points in turn.

SVD techniques exploit structure within the term/document matrix by locating co-occurring sets of terms. Clearly these term sets are replicating through the corpus since that is the precise statistical phenomena the SVD analysis detects. However it is not obvious that this replication is generally due to copying. Instances of precise copying occur when an in-reply-to thread includes elements of a previous post's text via the copying mechanism provided by the software system. Other instances of copying occur within a particular context or discussion thread when authors copy by hand words or phrases from previous posts into their new texts. More abstractly, replication occurs because certain memes are traveling outside of the NetNews environment (and thus outside of our means of analysis) and authors again act as copying agents injecting them into the corporal ecology. But, clearly, some re-occurrences are not due to copying but are a chance process where unrelated texts bring together similar words. The likelihood of such chance re-occurrences will be a function of the size and quality of our replicating unit. In summary, term-subspaces are instances of replication often due to copying.

The copying fidelity of a term-subspace is also a direct outcome of the SVD statistical analysis. But importantly, the copying fidelity of re-occurring term sets is not perfect across the entire corpus; the term sets will co-occur with some variation. These mutations are both changes *designed* by human authors and chance variation due to copying errors. In either case the mutations are *random* from the vantage of selection; in other words, human authors are not able to perfectly predict the adaptive significance of their inputted variations. These mutations work "backwards" into the actual term-subspace representation for a post organism. That is, a random mutation at the post level will actually result in a random mutation in the vector subspace representation (the memotype) for the post organism. In this way, the memes as represented in the memotype are subject to mutation.

Finally, we have elsewhere shown there can be a strong covariance between the replicative success of a cluster or thread of posts and the degree to which they express certain term-subspaces (Pocklington & Best [27]). In other words, a group of posts can increase its volume of activity over time by increasing the degree to which it expresses certain term sets within its post's text. This, then, is a covariance between the *fitness* of a population of posts and the expression of a particular *trait* as defined by a term-subspace. The demonstration of this covariance is critical to establishing that a replicator is subject to natural selection.

4.2 Quasi-species

If the term-subspace is a reasonable model for the meme then the term-subspace vector representation of a post is a good model of the post's *memotype*. Much as a genotype describes a point within genetic sequence-space for each organism, the memotype describes a point within conceptual sequence-space. By *sequence-space* we mean any of the search spaces defined by a replicator undergoing selection. Examples of sequence-spaces include the gene space, protein spaces under molecular evolution, and the meme space defined within a corporal ecology.

The notion of a *quasi-species* is due primarily to Manfred Eigen (Eigen, et.al. [12]; Eigen [13]). He states that the "quasi-species represents a weighted distribution of mutants centered around one or several master sequences. It is the target of selection in a system of replicating individuals that replicate without co-operating with one another (RNA molecules, viruses, bacteria)," (Eigen

[13]). One organism is a *mutant* of another if it is particularly close to the other in sequence-space.

We wish to group our posts into quasi-species. This requires finding groups of memotypes which are centered together within the conceptual sequence space. To do so we employ a simple clustering algorithm, the Nearest Neighbor Algorithm (Jain & Dubes [17]). We first normalize each post memotype to unit length; this amounts to discarding text length information and representing only the *relative* strength of each meme within a text. The clustering algorithm then considers each post memotype in turn. The current memotype is compared to each memotype which has already been assigned to a cluster. If the closest of such vectors is not farther than a threshold distance, then the current vector is assigned to that cluster. Otherwise the current vector is assigned to a new cluster. This continues until each and every vector is assigned to a cluster.

This process assigns each post to a quasi-species defined as those posts which are close to one another in conceptual sequence-space.

The overall aim in grouping organisms is to bring to light certain evolutionarily significant relationships. Clearly, our quasi-species clustering method is ahistorical; that is, it does not directly account for descent when grouping together text organisms. The extent to which such groupings are effective when studying the relatedness of natural organisms is a matter of continued controversy as can be seen in the debates of the cladists versus evolutionary systematists versus pheneticists. While we are currently agnostic to this controversy we do agree with an original claim of the pheneticists: the more traits used when assessing the relatedness of individuals the more accurate are the groupings (Mettler, Gregg & Schaffer [23]).

We are in the happy situation of clustering based on the complete memotype for each of our organisms. The result is that under empirical verification our clusters exhibit extremely strong historical relatedness. We have found that the vast majority of texts clustered together come from the same in-reply-to thread and thus are related by descent (Best [5]). But our clustering method has the added benefit of grouping related texts even when the in-reply-to mechanism is not used and, alternatively, breaking up texts that are within the same thread but are not semantically related. This is of value since many posters to NetNews use the in-reply-to mechanism to post unrelated texts or, alternatively, post follow-up texts without bothering to use the in-reply-to facility. Thus, we claim that our clustering mechanism, due to its access to hundreds of traits, is actually superior at grouping together both related and descendent texts than would be a simple reliance on the threading mechanism. The clustering method meets our goal of illuminating evolutionarily significant relationships.

4.3 Comparison to Natural Ecologies

We are describing phenomena within a corpus of texts in terms of population ecology and population genetics. This is not simply a metaphorical device; we believe that interacting populations of texts and their constituent memes are evolving ecologies quite exactly. However there are clearly a number of interesting differences between genes and memes (as here operationally defined), natural organisms and texts, ecologies and corpora. Important differences include the driving forces behind mutation within the texts and the role of self-replication and

lineage within the corpora. We leave to future work a more complete analysis of these differences.

5 Models for Interacting Populations

We now turn to studying the interaction between quasi-species of posts. We have so far only studied the pairwise interactions between post quasi-species. Similar pairwise interactions have been widely studied within theoretical ecology. Consider two interacting populations: one population can either have a positive effect (+) on another by increasing the other's chance for survival and reproduction, a negative effect (-) by decreasing the other population's survival chances, or a neutral (0) effect. The ecological community has assigned terms to the most prevalent forms of pairwise interaction, in particular:

- Mutualism (+, +)
- Competition (-, -)
- Neutralism (0, 0)
- Predator/prey (+, -)

(Pielou [25]; May [22]).

Our goal is to study the pairwise interactions of quasi-species within the corporal ecology with the hope of discovering some of these interaction types.

5.1 Time Series

To study how the interactions of populations affects growth rates we must define a method to measure a quasi-species' growth over time. Recall that a quasi-species describes a collection of posts which are close to one another in sequence-space. Each of these posts has associated with it a *timestamp* identifying when that text was posted to the system; in effect, its birth time and date. (Note that a post organism has something of a zero-length life-span; it comes into existence when posted but has no clear time of death.)

A histogram of the timestamp data is created with a 24 hour bucket size. That is, for each quasi-species we count how many member texts were posted on one day, how many on the next, and so forth through the entire population of texts. The datasets currently used span on the order of two weeks and consist of thousands of posts. So for each day a quasi-species has a volume of activity which can range from zero to 10's of posts. This rather coarse unit, the day, has been chosen to neutralize the strong daily patterns of post activities (e.g. activity may concentrate in the afternoons and drop off late at night; different time zones will shift this behavior and thus encode geographic biases). Thus the patterns of rise and fall in the volume of posts within a quasi-species when measured at the day level will, hopefully, reflect true changes in interest level and authorship activity rather than other external or systemic factors

5.2 The Test Corpus

Figure 2 is a typical graph for the volume of posts within a particular quasi-species over a period of ten days. This cluster was found within a corpus of all posts sent to the soc.women newsgroup between January 8, 1997 (the far left of the graph) and January 28, 1997 (the far right). In the figure the number of posts in a day is represented by the height of the graph. This particular cluster of texts exhibited an initial set of posts, a few days worth of silence, then a rapid building up of activity which then declined precipitously at the end of the dataset. The entire corpus used consisted of 1,793 posts over the same ten day period. The clustering mechanism arrived at 292 quasi-species the largest of which contained 103 posts.

Figure 2. Typical time series of posts to quasi-species. Time axis is measured in seconds since Jan. 1 1970.

5.3 Time Series Cross-correlation

To study the relationship between the time series of two populations of posts we use the cross-correlation function. The use of the cross-correlation to study bivariate processes, and time series in particular, is well known (Chatfield [6]). Each time series is normalized to be of zero mean and unit standard deviation; that is, we subtract off the mean and divide by the standard deviation. In this way, the cross-correlations will not be dominated by the absolute volume of post activity within some cluster and instead will be sensitive to both large and small sized clusters.

We assume the readers are familiar with the regular covariance and correlation functions. Then the cross-correlation for two time series, X and Y , is given by,

$$r_{xy} = \frac{Cov(X, Y)}{\sqrt{\sigma_x^2 \sigma_y^2}}$$

Here $r_{xy} = Cov(X, Y)$ and σ_x^2 and σ_y^2 are the variance of X and Y respectively. Note this formulation only considers the cross-correlation for a zero time lag. That is, it considers how the two time series are correlated for identically matching points in time. With a nonzero lag the cross-correlation would study cases when the two series might have correlations offset by some fixed amount of time. Since we group our time data into day-long chunks the zero-lag cross-correlation will be sensitive to covariances which have a time offset as large as 24 hours; this builds into the time series an adequate time lag.

When the cross-correlation between two sets of data is significantly different than zero it suggests the two sets of data have some relationship between them. A positive value means an increase in one series is likely to co-occur with an increase in the other series. A negative value means an increase in one series is likely to co-occur with a decrease in the other series.

Figure 3. The pairwise time series cross-correlation for 125 largest quasi-species clusters.

Figure 4 shows the pairwise cross-correlations for the 125 largest quasi-species clusters within our corpus. The diagonal represents the cross-correlation between a time series and itself which, as expected, is identically one. Note that the matrix is symmetric about the diagonal. The off-diagonal values range from near one to -0.26. The mean cross-correlation is 0.3. This value is quite high, indicating that most of these post clusters are somehow positively related. We suspect this high average cross-correlation is at least partially due to external or systemic affects which were not removed by the day-long bucket size. For instance, our analysis would be sensitive to

patterns due to the Monday-Friday work week common in the West. Further, some of this correlation may be due to a high level of mutualistic interactions amongst the posts. Clearly, the ideas conveyed within the soc.women newsgroup often share similar contexts. In our analysis this overall high correlation does not particularly matter since we are concerned with the *relative* cross-correlation -- that is, those that are the largest and those that are the smallest.

6 Negative Cross-correlations: Competition versus Predator/Prey

We have primarily studied those pairs of quasi-species with relatively strong negative cross-correlations; to wit, those where $r_{xy} \leq -0.2$. Note that in all such cases (there are 42) $P < .001$ suggesting that with extremely high probability the correlations are not due to chance. Figure 4 and Figure 5 plot two such interactions, both fairly characteristic of this population.

Figure 4. Volume of activity for two quasi-species. The cross-correlation between these two series is -0.26.

Figure 5. Volume of activity for a different set of two quasi-species. The cross-correlation between these two series is -0.23

Both of these figures demonstrate a clear negative covariance between the volume of activity of the two post clusters. This negative covariance is both statistically significant and visually compelling. But what do these graphs signify and can it be interpreted within the rubric of ecological interactions?

At first glance the interactions appear to be of a predator/prey variety; they have a (+, -) relationship to them. However, competition might also produce similar interaction phenomena if the competitors are operating close to some limitation or environmental carrying capacity. In such instances the relationship between population sizes will be a zero-sum game, when one goes up the other must come down. To be able to classify the interactions of Figures 4 and 5 we need to consider the qualitative details of these two interactions through direct study of the texts.

Recall that in the case of a predator/prey relationship, one population enjoys an increased growth rate at the *expense* of another population (e.g. one population feeds on the other). The presence of a relatively large population of predators will result in a diminished level of success for the prey (they get eaten up). Conversely, the relative absence of prey will result in diminished success for the predator (they have nothing to eat).

Now consider the case of competition. In competition two interacting populations inhibit each other in some way, reducing each other's level of success. This often occurs when the two

populations rely on the same limited resource. Unlike the predator/prey relationship where the predator requires the prey for success, with competition the two populations would just as soon avoid each other all together.

This pressure towards avoidance is the source of much ecological diversity since it propels populations to explore new and therefore competition-free niches (Pianka [24]). An ecological *niche*, for some particular species, is simply that collection of resources the species relies on. Interspecific niche overlap occurs when two or more species share one, some, or perhaps all of their resources. When those resources are scarce, interspecific competition will result. The *width* of a niche is simply a qualitative sense of the variety and number of resources a population makes use of.

6.1 Competition and Niche Behavior

We have studied the set of posts which make up the four quasi-species shown in Figures 4 and 5 in an attempt to qualitatively classify their interactions. The quasi-species of Figure 4 are made up of posts within a single thread. The subject line for these posts reads, ``Men's Reproductive Rights". In general, these posts are concerned with the responsibilities and rights of men towards their unborn children. The quasi-species displayed with a dashed line in the figure is centered around the use of contraceptives. It consists of a collection of posts wherein the authors debate who is most responsible, the women or the man, when using contraception. The quasi-species with a solid line deals instead with the use of abortion and whether the father has any intrinsic rights in deciding whether or not to abort an unborn child.

In Figure 5 these two quasi-species are also from a single thread. The subject line here reads, ``Unequal distribution of wealth?". This particular thread of discussion was rather large. In fact there was a total of 365 posts to this thread which our text analysis tools broke up into a number of quasi-species due to significant bifurcations of the topic. In other words, many parallel discussions occurred all within a single in-reply-to thread. The cluster of discussion shown with the solid line in Figure 5 centered around a debate as to whether the US military was a ``socialist collective". The quasi-species with the dashed line was a debate on the value of releasing the mentally ill from hospitals. Clearly, these two debates are quite dissimilar even though they span the same set of days and are posts to the same discussion thread.

The quasi-species of Figure 4 are different but related discussions. Those of Figure 5 are different and not clearly related. Still, we believe that both of these sets of interactions demonstrate elements of competition. Within the texts there is no evidence of predator memes; in Figure 5, in fact, the memes seem entirely orthogonal to one another.

However, in both examples the memes are competing for the same collection of human authors who must act as their agents if they are to propagate and succeed. This seems even more likely when we consider that all these posts are to the same newsgroup which due to its narrow subject area supports only a limited supply of human posters. Moreover, each pair of interactions are confined to a single thread of discussion, which again has an even more limited set of potential human authors since users of the NetNews system often zero-in on particular threads they find interesting and ignore others. After inspecting most of the interactions which demonstrated

strong negative correlations we observed no examples of predator/prey interactions but many instances which appeared to be examples of competition.

6.1.1 Statistical Artifacts

We computed the cross-correlation between 125 different clusters, arriving at 15,625 different correlations. It is possible, therefore, that the cross-correlations with large negative values exist simply by chance; they represent the tail of the distribution of correlations.

However, we believe that our qualitative analysis provides strong evidence that these negative correlations are *not* artifacts but are indeed due to an interaction phenomena between the two quasi-species. The two pairs of quasi-species described in detail above demonstrate this point. The likelihood that two quasi-species be brought together by mere chance *and* both be from the same thread (out of 324 threads within the corpus) seems vanishingly small.

6.1.2 Competition

We now will test our theory that these interactions are of a competitive nature. Again recall that competition is often caused by populations existing within the same (narrow) ecological niche. What makes up an ecological niche for a meme within NetNews? We argue that the newsgroups themselves make up spatially distributed ecological niches. Since there is relatively little interaction between newsgroups (save the phenomena of cross-posting) we would expect these niches to behave something like island ecologies -- they remain relatively isolated from each other. Within a single newsgroup (which is all we have studied so far) niches might be described by threads of discussions. As previously stated, we have found that individual posters to the system tend to become involved in particular in-reply-to threads which interest them. Thus the memes within a particular thread make use of a set of human resources which is smaller than the entire set of potential human resources available to the newsgroup. These resources define the niche.

We theorize that cross-correlations which approach -1 in our corpus are examples of competition, and competition will be more likely between populations which are posted to the same threads and thus have overlapping niches. The most direct way to test this theory is to see if negative cross-correlations between two quasi-species correlates with the degree to which they post to the same threads. For each of the 125x125 pairwise interactions we computed the number of threads each of the quasi-species pairs had in common and divided that by the total number of threads posted to by each quasi-species. For example, one quasi-species may contain posts which went to two different in-reply-to threads. Another quasi-species may have posts which span three different threads one of which is identical to a thread within the first group. So this pair of quasi-species would have posted to a total of four different groups one of which was shared. Their relative niche overlap would therefore be 0.25.

We calculated the correlation coefficient between the negative cross-correlations of Figure 3 and the percentage of thread overlap between these quasi-species pairs. We found this correlation to be -0.04. While this correlation is statistically significant ($P < .001$), it is not very pronounced. The negative sign, though, does indicate that as the level of competition increases (a negative

cross-correlation) the percent of overlap of their niche also increases (a larger positive shared thread percentage).

This small correlation coefficient may be due to a small signal/noise ratio. Since most pairwise interactions result in small correlations, the relative number of large negative correlations is quite small. The number of interactions grows with the square of the number of quasi-species. We suspect that a simpler experiment which grows linearly with the number of quasi-species will have a better signal/noise ratio.

We have studied the correlations between the absolute number of in-reply-to threads a quasi-species is posted to and the average degree to which the quasi-species finds itself correlated with other clusters. Our hypothesis is that the absolute number of threads a quasi-species is posted to will be related to the average degree of competition the quasi-species experiences in its interactions. Since the variety of resources used by an entity defines its niche, if a quasi-species is posted to a relatively small number of threads then it exists in a narrow ecological niche. Should there subsequently be any interspecific overlap of these narrow niches, scarcity will result in competitive encounters. We computed the correlation coefficient between the total number of threads within a quasi-species and its *average* cross-correlation value. The correlation coefficient here is 0.25. Thus, as the number of threads within a quasi-species increases (the set of available resources is widened) the average level of competition diminishes (the mean pairwise cross-correlation also increases). This correlation is statistically significant ($P < .001$) and rather pronounced.

We further computed the correlation coefficient when the absolute number of threads was normalized by the size of the quasi-species. We might expect that the number of threads employed by a quasi-species would grow with the number of posts within that quasi-species. In other words, as a quasi-species gets larger the number of threads increases too. This might affect the analysis above such that instead of measuring niche width we were simply measuring quasi-species size. Dividing out the size amounts to computing the *average* number of threads employed by a post for a given quasi-species. When this set of values was correlated with the mean cross-correlation we arrived at a nearly identical coefficient as above and again clear statistical significance. Thus quasi-species size is not a major factor in level of competition.

7 Conclusions

We have described a set of text analysis tools, based primarily on Latent Semantic Indexing, which distill replicating memes from a corpus of text. We have trained this analysis system on a corpus of posts to NetNews. This makes up a corporal ecology where the posts are organisms, NetNews is the environment, and human authors are a scarce resource. We argue that this represents an important bridging of text analysis and the Alife research program. Further, it amounts to a novel shift for Alife research -- rather than synthesizing life-like agents we are analyzing a pre-existing environment and discovering life-like behaviors.

In results reported here we group together posts which make use of similar sets of memes. These groups, clouds within a conceptual sequence-space, describe quasi-species. For each quasi-species we compute its time-wise volume of activity by histogramming its daily post levels. We

then study the pairwise interaction between quasi-species by computing the cross-correlations between their time series. In our corpus, strong negative cross-correlations signify conditions of competition between the interacting populations where the quasi-species are competing for a limited set of human authors. Furthermore, quasi-species with relatively narrow ecological niches, those which make use of a small number of in-reply-to threads, are more likely to be in competition with other quasi-species. This behavior is analogous to what is found in natural ecologies (Pianka [24]).

Why do these quasi-species compete? Qualitative analysis of the posts, such as those described in the previous section, shows that many competing quasi-species are posts sent to the same or similar threads. Competition is over the scarce authorship resources within these specific thread niches. Over time a particular thread of discussion may bifurcate into two or more internal themes which then proceed to compete for "air-time" within the thread.

Acknowledgments

We thank the two anonymous reviewers for their helpful critique of this paper. We gratefully acknowledge the significant input of Richard Pocklington to this work and his careful reading of a draft of this paper. Laurie Hiyakumoto also gave very helpful comments on a draft of this paper. We thank Bernd Schoner and Michael Patrick Johnson. Finally, the author is pleased to thank the sponsors of the MIT Media Laboratory for their financial support.

**A LETTER ON:
MEMES ON MEMES
A CRITIQUE OF MEMETIC MODELS**

By
Michael L. Best
Media Laboratory,
Massachusetts Institute of Technology,
Cambridge, Massachusetts 02139, USA.
mikeb@media.mit.edu

In these pages and elsewhere a lot has been made of the "new science of memetics". I argue that this phrase misleads. First, work on evolutionary models and indeed replicator based models of cultural phenomena is not terribly new, though too much current work in the field ignores this history. Second, the scientific progress made in the area, if by science one means formalized models, is often quite immature. An exemplar of these weaknesses is the recent contribution to this journal by Aaron Lynch (1998).

Evolutionary theories of cultural change pre-date Darwin himself. By the turn of the century evolutionary theories had established themselves as dominant models of epistemology (e.g. Spencer 1864; see Campbell 1974) and language change (e.g. Lyell 1863; Darmesteter 1886; see Nerlich 1990). In other words, evolutionary theories of "ideas" dominated late nineteenth century thought and are certainly no newer than evolutionary theories for organic biology.

Examining the history of organic evolution one sees that theories of the mechanisms for change (namely natural selection (Darwin 1859)) predate modern theories for transmission (namely population genetics (Haldane 1932; Fisher 1930)). The same seems to be true for cultural evolution with theories for change established well before transmission models. Nonetheless, in the last twenty years a collection of formal replicator based transmission models for cultural phenomenon have been proposed (Cavalli-Sforza & Feldman 1973; Lumsden & Wilson 1981; Cavalli-Sforza & Feldman 1981; Boyd & Richerson 1985; Barkow 1989; Durham 1991; reviewed in Durham 1990).

Dawkins (1976), in a nice turn of phrase, proposed the word "meme" to describe replicating cultural units. However, other terms have also been put forth for this purpose including "cultorgen", "symbol", "culture-type", and "theme". Lynch (1998) claims to introduce a new neologism, the "mnemon", though in point of fact this term was first proposed by Campbell (1974). Debate continues on what is meant exactly by these various terms.

In his recent contribution, Lynch (1998) proposes a formal transmission model for population memetics. Thus, he is working within the mode of, in particular, Cavalli-Sforza, Feldman, Boyd, and Richerson; though he does so without reference to any of their work. He devotes some time to the description of differential equations which aim to model the dynamics of two distinct memes which vie for hosts within a population.

A formal model should aim to describe empirical data (present or sought after) and should shed explanatory light on some phenomena. Lynch's do neither. This is due to a number of problems - the wrong tool, focused at the wrong areas of the problem, creating a model which is too complex to make progress with, which encapsulates a set of assumptions that are neither stated nor justified.

& + \int_0^{\infty} \gamma_{12}(p,a)N_1(p,t)N_2(a,t)dp \\
& + \int_0^{\infty} \frac{\beta_{12}(p,a)N_1(p,t)N_2(a,t)}{N(t)}dp \\
& - \alpha_1N_1(a,t) + \alpha_2N_2(a,t) \\
& + \frac{\partial}{\partial a}N_1(a,t) - M_1(a)N_1(a,t)
\end{aligned}$$

Equation (1)

Consider just the first term to Equation 1, taken from Section 16 of Lynch's paper. Here Lynch describes the change with time, t , of the acquisition of a particular meme in a population of a given age due to transmission from parents. This is expressed in terms of the number of parents at time t of some particular age p , $N_1(p,t)$, the number of offspring they have of the appropriate age, $R_1(p-a)$, and the ratio of parents who possess the meme that transmit it to their offspring given these ages, $K_{11}(p,a)$. Note that this is given as a ratio and not a probability resulting in a deterministic model. Lynch chooses to model everything as continuous functions with time or age and to integrate over all age groups whenever he wants a fixed number. The misapplication of the continuous domain is evident by the fact that even within his formalisms Lynch is compelled to discretise time. Here, $K_{11}(p,a)$ is the ratio per year of a transmission event and not a continuous ratio over time. I am not sure what it means to integrate over continuous ages a value measured in discrete time steps and to, subsequently, differentiate that over continuous time.

This model, naturally, focuses our attention on its parameterized spaces. Namely, it asks us to consider how transmission dynamics change with respect to the age of parent versus offspring. I question the value of this particular focus of attention. While age specific models might indeed be worthy of exploration we are offered no arguments as to why this particular age parameterization is relevant. In particular, why would the age of the parent be given such attention? While Lynch correctly states that a model must hide certain elements while exposing others I question those he has chosen to expose. Other factors to consider include the relationships between model and learner (parental and non-parental models), the numerical relationships between model and learner, the complexity of societies, spatial distributions, modes of communication, and so forth. Further, the model makes a number of assumptions which go unstated and unsupported. For example uniparental transmission; there is no consideration of two parents. Such a simplification demands defense and should not be included within the model without comment.

Consider again, $K_{11}(p,a)$, the ratio per year of a transmission event between a parent of age p and an offspring of age a . For this model to be of explanatory value we need to understand what this ratio K_{11} might look like in two-dimensional space. What would it mean for it to be concave, convex, increasing in a , increasing in p , and so forth. These are the sort of questions whose answers might provide value to these models. But Lynch provides no such explanation. He simply states the existence of this ratio, K_{11} . But it is this very ratio which goes to the phenomena Lynch presumes to be describing – namely, what are the dynamics of transmission between parent and offspring. From the vantage of population memetics, the action is in the likelihood of and factors around successful transmission. Lynch's formulation couches that phenomenon in a quite complex set of continuous functions who's born when and how does that vary with transmission. But it does not make any explanatory progress towards understanding these transmission dynamics. Moreover, it presents a deterministic ratio for the transmission event without offering any hope for actually arriving at this fixed (given a set of ages) rate of transmission. This side-steps what should be the central question of study what is the probability distribution of these transmission events given a sound parameterization.

The overall complexity of Lynch's differential equation also is a drawback. It would be useful to understand, even within his parameterized spaces, what factors would lead to fixation of one meme versus another, what factors would lead to a frequency dependent mix, and so forth. However the sheer complexity of the model makes analytic (and indeed numerical) progress unlikely.

In Section 5 Lynch also presents a more simplified method to symbolize memetic transmission events. While the simplicity I applaud I find the overall mechanisms implausible. Lynch proposes to model the transmission of a "negatively defined mnemonic". This is, apparently, some sort of "forgetting" event where a meme is removed from an agent's memory. Lynch supports this mechanism through an argument by definition he claims that this is consistent with his usage of "memory abstraction". While no doubt one could build a consistent model of the transmission of forgetting that does not make it a mechanism important (indeed even present) within human cultural evolution. Lynch goes on to claim that this is why birth control is a successful meme; it is easier to learn than to forget such concepts. Here we see how an implausible formal model leads to an unjustified conclusion. It seems far more likely that the concept of birth control

maintains itself due to its epistatic co-adaptive relationships to other meme complexes which render it stable in the presence of small numbers of competing memes. But, again, this is the very sort of question that Lynch's models should aim to investigate; our arm-chair theorizing amounts to nothing against well supported models and, of course, empirical data.

My critique of this model is towards a broader purpose. I hold building a science of memetics as an admirable project. Slow progress towards such a science has been made as evidenced by much of the cited literature. But the misapplication of science, that is formal models, does damage to the program. Mathematics, even if it is correct in some formal sense (and even this I question in the case of Lynch), is not of use unless it helps to explain the phenomena in question.

There exist a few practical methods to insure progress with formal modeling. Perhaps the most critical is an open and lively dialogue on these very matters; I hope this essay can help to stimulate such a discussion. Second, it is best to test formal models on real empirical data. In this way predictions can be verified, fit can be measured, hypotheses can be tested. Sadly, empirical data is not always available. Alternatively, computational simulation and analysis can act as a surrogate for empirical data. In this case, hypotheses are stated, and analysis (numerical or symbolic) can serve to test these hypotheses. For instance, if Lynch is keen to employ an age-specific model, he might study what relationships between ages and transmission probabilities would result in points of fixation. Lynch, it must be said, makes some of these exact points himself; he argues for the value of falsifiable models. But, sadly, he does not take his own advice and try to support (or falsify) his own arguments.

Finally, the scientific method relies heavily on an appreciation of past art. Lynch would do well to study the transmission models (which include continuous-time models) within the literature (if he has studied them he would do well to cite and make use of their results). Indeed, cultural transmission is not the only important related work. I find myself, for instance, looking to research on social learning in animals, behavioral ecology, artificial life, and so forth.

Acknowledgements

I would like to thank Richard Pocklington and Hans-Cees Speel for their comments on a draft of this letter.

THE LIFECYCLE OF MEMES

By

Henrik Bjarneskans, Bjarne Grønnevik and Anders Sandberg

Abstract

Memes, self-reproducing mental information structures analogous to genes in biology, can be seen as the basis for an explanatory model of cultural and psychological behaviour. Their properties and effects are evolutionary conditioned and ultimately seek to promote their replication. To survive in a context the memes must meet certain conditions. We abstract a model of these conditions and use it to analyse three well-known memes: the "Kilroy was here" graffiti, urban legends and Christianity.

1. What is a Meme?

Memes were originally described by Richard Dawkins in his book *The Selfish Gene* (1976) [1]

A unit of cultural transmission or a unit of imitation

Examples of memes are tunes, ideas, catch-phrases, clothes fashions, and ways of making pots or building arches. Just as genes propagate in the gene pool via a process which, in the broad sense can be called imitation. If a scientist hears, or reads about, a good idea, he passes it on to his colleagues and students. He mentions it in his articles and his lectures. If the idea catches on, it can be said to propagate itself, spreading from brain to brain.

What makes the meme concept so powerful is its close analogies to the theory of natural selection. Natural selection occurs whenever the following conditions exist (Dennet 1990):

- Variation: a continuing abundance of different elements.
- Heredity or replication: the elements have the capacity of creating copies or replicas of themselves.
- Differential "fitness": the number of copies of an element that are created in a given time varies, depending on the interaction between the features of that element (whatever it is that makes it different from other elements) and features of the environment in which it persists.

This is a quite general definition which is not limited to biology, and suggests that memes are subject to natural selection: they vary (due to "mutations" in transmission or mental storage, plus deliberate changes), they replicate (by definition) and have differing fitness. This leads to phenomena of competition, co-evolution, population dynamics and adaptation surprisingly similar to their biological counterparts. The set of shared memes form the memepool (in analogy with the genepool).

It should be noted that human decisions are part of the memetic selection process; from the perspective of the memetic ecology humans and human behaviour corresponds to the climatic and geological environment of biological life. In the meme perspective, it is more accurate to say that the message has evolved into its form in order to encourage people to spread it than to say that people have selected or 'bred' the message into its form.

Although people often make the decision to spread a meme or not consciously, this process is influenced by the meme. Some memes are viewed as important, and hence spread to others after a conscious and sometimes rational evaluation; some memes exploit aspects of cognition or emotion to bias their hosts to spread them. Natural selection favors memes that are good at reproducing, which suggests that in time there will exist many memes that are very efficient replicators. Their accuracy is irrelevant for their survival, only their ability to replicate and find new hosts; memes that interest people and encourage them to spread the meme will thrive at the expense of less attractive versions.

What makes the meme perspective so interesting is that it suggests that some of what we have learned from biology can be applied to human psychology. Dawkins points out that "a cultural trait may have evolved in the way it has simply because it is *advantageous to itself*". Gross (1996) says

The main shift in thinking that needs to take place is to look at the spread of the legend not so much from the point of view of the people who propagate the warning, but from the point of view of the warning itself.

In memetics, ideas are viewed as almost independent creatures in a symbiotic relationship with human minds and cultures.

1.1 Defining Memes

The meme concept is somewhat slippery to define, and there is an multitude of definitions ranging from the very wide to the very narrow. The definition of meme we will use in this essay is

A meme is a (cognitive) information-structure able to replicate using human hosts and to influence their behavior to promote replication.

This is a somewhat strict definition, since it excludes many structures able to replicate without influencing host behavior or using non-human hosts such as chimpanzees, dolphins and computers. It can be seen as a subset of the more general memes described by Dawkins.

Memes do not only influence behavior to promote replication, but many of the most successful memes have other side-effects (for example, being able to invoke various emotions) or promote their replication by being useful or through other features (like parasiting on other memes, e.g. parodies and imitations); using a biological analogy one could say symbiotic memes spread mainly using their usefulness, while parasitic memes compel the host to spread them. This compulsion can be more or less subtle, ranging from explicit orders like in chain letters ("Send

ten copies of this letter to your friends") to implicit influences that link with our attitudes like the "Save the whales" meme described in (Hofstadter 1985, p. 55).

It is quite common that memes are confused with ideas/thoughts. Both are cognitive structures, but an idea is not self-replicating and is spread passively (i.e. for extrinsic reasons) if it is spread beyond its initial host at all. The difference is sometimes hazy; the idea "Isn't it time for us to eat?" can easily spread in a small group, but will not spread well outside the group and will disappear once the question is settled, while a meme usually can spread generally and does not have any limited lifespan.

It should also be noted that memes often form meme complexes, groups of memes mutually supporting each other and replicating together. The dividing line between a meme and a meme complex is yet again diffuse. In this text we will not try to distinguish between the two.

1.2. Issues in Memetics

1.2.1. The Meme - Gene Analogy

Much fuss has been made over this analogy since it was introduced by Dawkins in his "The Selfish Gene". When Dawkins introduced this analogy it was to give us a meaningful comparison in the light of which we would better understand the concept of memes. This was done to help our *initial phase* of understanding; unfortunately, many memeticists has not left this area. Many writers have scrutinized the comparison with the gene to see if it really is analogous or not, i.e. Hans-Cees Speel (1996). Although this has provided interesting reading we feel that it is a bit beside the point. The importance of memes lies not in whether they are mental copies of the genes and obey the same laws as the genes do or don't, but rather in how they work and what they are capable of (and not capable of). We do not feel that you can reach a complete understanding of this only by comparing them to other things. You have to study the idea of memes *in itself*.

This is why we have chosen to make a detailed study of what we can call "the memetic life-cycle", to try to discover its inner memetic workings. Our aim is to find a model that, whether analogous to the genetic life-cycle or not, is sound and supported by studies of existing memes.

1.2.2. Definitions

In the field of memetics there are a couple of different definitions of "host", "vector" and "meme" around, and there is a tendency to make these wide to the point of being meaningless. We want operational definitions that are usable and still distinct. Therefore, in this paper, we are going to use the words "host" and "vector" as such (meme has already been defined above):

Host: A host must be able to possess at least *the potential capacity* to elaborate on the meme and to perform those cognitive tasks connected to the meme that we normally refer to as "understanding". This means that only humans can be hosts (animals can perhaps become hosts for simpler memes, but we will not discuss this here), at least until the development of artificial intelligences reaches further.

Vector: A vector is anything that transports the meme between hosts without the capacity to reflect on the meme. Examples are a wall, a voice, an email-program, or a picture. Can a human be a vector? Yes she can, if she lacks the cognitive capacity (or interest) to elaborate on a specific meme. Then she is just a non-reflective carrier of the meme, much the same as a book. Note though that the human vector is still a potential host - or *inactive* host (Grant, 1990) - for the meme, should she suddenly choose to analyze the meme (in its widest sense) or achieve the contextual understanding which would make this possible.

1.2.3. The Conscious Meme

It is worth noting that although the terminology used in genetics and memetics sometimes seems to indicate that genes and memes act upon their own conscious will, this is of course not the case. Genes and memes are not conscious, and they do not have a will as such to act upon. But it is practical and economical to speak as if they do, since their behavior follows such patterns.

This way of speaking can be seen as lazy shorthand; "a meme wants X" means "the fitness of a meme is enhanced by X".

2. The Lifecycle of Memes

Memes have a life-cycle similar to parasites (Fig 1). During the transmission phase of the meme it is encoded in a vector, such as a spoken message, text, image, email, observed behavior or slab of stone. When a potential host decodes the meme (reads the text, hears the message) the meme may become active and infects the person, who becomes a new host (the infection phase). At some point the meme is encoded in a suitable vector (not necessarily the same medium it was originally decoded from) and can be spread to infect new hosts.

Fig 1. A simple model of the lifecycle of a meme.

This division of the lifecycle makes it easier to discuss memetic selection criteria, such as the list proposed by Heylighen (1994):

- Contribution to individual fitness (how the meme enhances the fitness of its host)
- Reliability of predictions
- Learnability
- Ease of communication
- Tendency to be transmitted
- Conformity pressure ("meme selfishness"; how the meme interacts with other memes in the host)
- Collective fitness (how the meme enhances the fitness of the group or social system of its hosts).

or other, more elaborate divisions such as (Hale-Evans 1995).

In the following we will discuss the intrinsic factors of the meme that contributes to its fitness, and those external factors that mesh with them. We will look at the factors that help or hinder a meme in each of the phases of its lifecycle as depicted in Figure 1. These factors will be summarized below in an extended version of the model (Figure 2).

A successful meme will be good at exploiting these factors in its environment, while memes that cannot exploit them well will be out-competed and eventually go extinct. If one phase presents an insurmountable obstacle to the meme, it will be unable to reproduce and survive. This allows us to make estimates of memetic viability.

2.1. Transmission Phase

In the transmission phase the meme is encoded in a vector, some kind of information- carrying medium. Which medium is used strongly depends on the meme, both how it *can* be expressed (influenced by its complexity, the need for copying-fidelity and the requirements of its semantic form) and how it *wants* to be expressed. Often the medium is strongly linked with the meme or an actual part of it, as in the case of the "Kilroy was here" meme where part of the meme is the graffiti itself, suggesting the possibility of scrawling it on some suitable surface; "The medium is the message" as Marshall McLuhan put it. Memes are able to shift between media, sometimes with a mutating effect on the meme (such as the major differences between the *Hunchback of Notre Dame* by Victor Hugo and the same story told by Disney).

It is interesting to see how memes and media have co-evolved: many media have been developed as memetic vectors, able to encode memes indefinitely and with a high degree of exactness, while memes have evolved to use them and exploit their peculiarities.

Dawkins (1976) suggests three qualities of a meme that gives it a high survival value: longevity, fecundity and copying fidelity. Longevity and copying-fidelity are most significant in the transmission phase (although longevity can also be seen as the meme's ability to remain in memory for a long time), and are strongly linked with the properties of the medium. Heylighen

(1994) also points out that ease of communication increases memetic fitness, either through creating salient behaviour that is easy to imitate or by being able to be clearly expressed.

2.1.1. Reproduction Ability

The more copies of itself a meme can encode in vectors, the higher fitness does it have (by definition). This implies that memes would thrive in media where it is easy to make numerous copies and distribute them widely. From a memetic standpoint, the ideal medium is a broadcast medium where many copies can be made cheaply. If it is one-to-many such as radio, then the memes of the broadcaster will spread with little feedback; this supports a less diverse memetic ecology than a many-to-many network, but also promotes the memes of the sender more strongly. In a many-to-many medium such as the Internet there are multiple meme sources, and the memetic diversity is high.

Two typical examples of the influence of reproduction ability are "xeroxlore" ("You don't have to be insane to work here, but it helps") that can be found in almost every modern office thanks to photocopiers, and Internet spams ("Make Money Fast!") that thrive in the broadcast environment of the Internet; neither meme would be possible without easy copying.

2.1.2. Copying Fidelity

While mutation leads to evolution, it also risks to destroy or degrade the meme. Just as in biological organisms a balance has to exist between evolvability and copying fidelity (Kelly 1994, p. 537). Many memes have properties that enhance their copying fidelity, often by making errors in encoding noticeable (note the analogy to error-detecting and -correcting codes cf. (Biggs 1985)).

2.1.2.a. Non-Alteration Policy

Some memes explicitly forbid any alteration of themselves, such as the instructions given in chain letters, the copyright notices of public domain information (only unaltered copying is allowed) and many sacred formulae that warn of awful consequences if they should be altered. They increase their copying fidelity by making the host careful in encoding them well.

2.1.2.b. Structure

Cohesiveness may also improve copying fidelity by introducing patterns that support the copying and transmission process. Poetry becomes stable by using rhyme and meter, since mutations create obvious errors that can be corrected. Many memes contain noteworthy features such as humor, commonly known symbols or repetition (cf. the common use of groups of three in myths). Incidentally, these properties also make memory encoding and retrieval easier.

2.1.2.c. Simplicity

Another way of achieving high copying fidelity and a low mutation rate is simplicity. A short meme is less likely to be changed, and may even be "brittle" - any change makes it obviously

unusable to the encoder, and thus prevents mutation. Longer or larger memes can survive only in media with high copying fidelity and low copying costs.

2.1.2.d. Repetition

A fourth way of achieving a low mutation rate in the vector form is to concentrate on making potential hosts understand the meme, not to ensure perfect copying fidelity (which may not be possible in some media, such as the spoken word). By repeated exposure, a potential host will not only recreate the meme from possibly distorted encodings, but also be more likely to become infected. This is an especially useful strategy for meme complexes, large memes and memes with high abstractability since they can (and often must) be transmitted piecemeal.

2.1.3. Survival

The meme has to be able to survive in the medium, and the medium itself has to survive. Memes that can be encoded in durable vectors such as books, great art or major myths can spread almost unchanged for millennia, while memes encoded in ephemeral vectors such as the spoken word have to spread from host to host quickly and are also more likely to mutate into new variants.

2.1.4. Abstractability

Some memes can be encoded in a large variety of vectors, while others are fixed in a single medium. Canonical examples are funny stories, which can be spoken, acted, written or drawn, and graffiti, which is its own vector.

A meme that can pass from one medium to another can spread more easily and change into forms more able to infect new hosts, but is of course more sensitive to mutations. One strategy that works well together with high abstractability is the understanding- repeated exposure strategy, since it decreases the mutation rate and partially relies on the abstractability of the meme.

2.1.5. Decodability

Finally, a meme must ensure that its vector is possible to decode for new potential hosts. Most artificial media used for information and meme storage are intended to be easy to decode (Dawkins would say there is a memetic selection effect here: the memes of creating media that have low decodability would not be replicated as much as the memes of creating high-decodability media, which would tend to dominate), but many natural media such as behavior are not necessarily easy to decode. Observed behaviour can be viewed as a medium of meme transmission; this is essentially social learning theory (Bandura 1977) restated in a memetic framework. Many behaviors (e.g. gestures such as applauding) are learned this way with no verbal explanation even at an early age and reinforced through positive feedback.

A classic example of behavior transmission (although somewhat outside our strict definition of memes) is the spread of food-washing observed among Japanese monkeys: in 1952 monkeys on the island Koshima were given sweet potatoes by researchers. The potatoes were left on the

beach, and while the monkeys enjoyed the food they disliked the sand. One monkey, 18-month Ima, found that she could get rid of the sand by washing the potatoes in a stream or the sea. Other monkeys observed her behavior and repeated it as they found that it had positive results, until after a few years practically all monkeys, except the oldest, washed their food [2].

It should be noted that some memes increase their fitness by making decoding *harder*. Belonging to an exclusive group increases self-esteem; memes that can only be decoded by some hosts will thus provide them with a feeling of superiority (whose strength depends on the exclusiveness of the meme and other factors) and thus gain a certain infective advantage. The popularity of secret languages among children and secret orders among the upper classes demonstrate this.

A hard-to-decode meme requires more mental activity to decode, which makes infection more likely if the salient aspects of the meme can be reasonably sure to be decoded in the process, and suggests (through cognitive dissonance) a higher value of the meme. If the meme can also be interpreted in several or arbitrary ways, it is also more likely that potential hosts settle for interpretations that fits their attitudes the best. An example of this class of meme is alchemical writings, which are heavily cloaked in symbolism and riddles: the bait is the promise of powerful knowledge (which doesn't have to be delivered if the riddles are hard enough), the meme itself is the symbolical language of alchemy and the hook that leads to transmission is the self-enhancing feeling of spreading esoteric wisdom to the select few who can understand it.

2.2. Decoding

Decoding is when a potential host interprets and restructures the information pattern of the meme in the vector by perceiving and understanding, and thus creates a mental copy of the meme. In other words, if a meme is to infect a host, it must first be perceived by the host, then decoded to fit the host's schemata. The possibility of infection arises after decoding. Many of these decoding processes are automatic and/or subconscious.

2.2.1. Understanding and Interest

If the host is incapable of understanding the meme or even incapable of perceiving it in the form in which it is being transmitted, the meme will not proceed to the infection phase. Memes that in some way promote their perception, by being encoded in a noticeable vector, by containing strong emotional content or otherwise arouse interest will have an increased likelihood of infecting the host.

Understanding is in this case not limited to conscious understanding, as in the case of copying a popular fashion, neither is it always necessary that the host acquires a complete and correct understanding of the meme (see the "Kilroy was here" example) if it can later be fully decoded using the repetition strategy.

2.2.2. Pro- and Contra-memes

There is a possibility that the potential host is infected by memes with the function of counteracting or helping the current meme. Such memes are often symbiotic parts of larger

meme-complexes, with the function of indirectly promoting itself through the promotion of its meme-complex. A typical example is religions, which promote trust in the teachings of the religious authorities (pro-memes) and often contain memes denouncing competing religions as heresy (contra-memes).

Contra-memes act by making their hosts automatically reject memes that do not fit the dominant cognitive structures. Often they act by creating a strong emotional response or attributing negative traits to the meme (knee-jerk reactions). In the same way pro-memes create positive attributions of certain memes and ease their assimilation.

2.3. Infection Phase

After successful decoding the meme becomes part of the host's mental structures, and this is called infection. A person who does not remember a meme at all is not infected. A person that does remember a meme but whose behavior is not affected has thus become a human vector. A person whose behavior is affected by a meme has been actively infected and can potentially transmit it to other hosts.

The following factors will influence whether an *active* infection will occur or not.

2.3.1. Ability to Fit Cognitive Structures

The meme must fit into the present schemata of the host to be seriously considered. A meme that assumes that God exists will probably not be successful in the mind of an atheist. To convince this person, an extensive set of pro-memes would have to be successful in infecting the atheist, thus reconfiguring the cognitive structures of its host to that of a religious person.

2.3.2. Threat/Bait

Most memes use threats or temptations to make the host accept the meme. If the meme appears to provide an advantage over previous memes, it can replace them (but it should be noted that older memes may have infiltrated the motivation structure of the host, making her unwilling to switch views anyway). Threats are even more potent, since potential risks are evaluated more strongly than potential gains (Kahneman and Tversky 1982), which means that a threatening meme often can out-compete a tempting meme.

Often threats and baits are combined to further enhance the meme. Many religions use this in propagating themselves, promising the faithless a hot afterlife (threatening) and the faithful a fluffy and light one (tempting).

2.3.3. Storage

If a meme is to be spread by a host for a long time, the host must remember the meme. If a host is infected and later forgets the meme and/or stops acting out the new behaviour before the host has spread the meme on, the host has not done the meme any more good than if the host had not been infected in the first place. Thus successful memes encourage permanent or long-lasting

changes in the host. Note that it is not necessary for the hosts to remember the meme itself, just change their behaviours in a way that will promote the spread of the (reconstructed) meme. This can be achieved in several ways:

2.3.3.a. Assimilation/Accommodation

If the meme can be assimilated into existing schemata, it will be supported by them. If the meme can somehow force an accommodation, it will have even better chances of becoming a vital part of a long-lasting mental structure (and this also gives it an excellent position from which to act as a contra- or pro-meme).

2.3.3.b. Elaboration

Something that a host actively thinks about is less likely to be forgotten, and also more likely to influence behaviour. Thus memes that encourage thinking or fantasising about themselves or related concepts have increased chances of survival. Rituals and ceremony are often powerful reminders of the meme.

2.3.3.c. External storage

Since human memory tends to be rather uncertain, external memory aids can also aid memes greatly not just as vectors, but as memory feedback.

If a host is infected by a scientific meme-complex he will be encouraged to read books relating to the meme complex. The host becomes likely to learn more and more about the theories rather than forgetting parts of them, and should he forget something relevant he can look it up again; the books can serve as memory feedback loops and also act as vectors for other parts of the meme-complex causing further infection.

2.3.4. Storage Time

The longer a meme infects its host, the more chances it has to be spread on to other potential hosts, but there is also an increased risk of mutation. Some memes have limited lifetimes determined by outside factors, such as millennial memes ("The world will be destroyed on Tuesday!") whose fitness decrease significantly after a set date (but before that date gain in fitness by being actual and urgent). There are examples of computer viruses that destroy themselves after a predefined goal, like making X copies of itself or residing for X days in the computer (Dawkins 1993), which are surprisingly similar to the instructions of chain letters. After making the copies and sending them, the host is no longer instructed to spread the meme.

2.3.5. Survival

Survival of the meme depends upon whether or not the meme can handle or use the following problems in the host mind:

2.3.5.a. External Contra-Memes

An infection may be subject to contra-memes, trying to "cure" the infection after it has become active, as opposed to a contra-memes struggle to prevent an infection in the decoding phase. A contra-meme does not have to be specifically directed towards its counterpart, it only has to counteract the intention of its counterpart. Survival requires a meme to withstand their attacks. Many obviously false but firmly believed memes can be surprisingly tenacious in the face of opposing evidence (Gross 1996).

2.3.5.b. Immunity

If a meme can make the host assimilate or accommodate contra-schemata to protect itself, it is less likely to have to deal with external contra-memes or competitors. The meme complex of atheism is likely to give its host a defense against any religious meme complex. This defense is practically an immunity since a convinced atheist won't even consider listening to a religious host with an open attitude. The opposite seems to apply too.

2.3.5.c. Universality

If the meme is widely enough defined, or is a generally accepted concept, it can assimilate all other memes because it is more general and can be used as a context which can explain all necessary functions. Many religions claim to explain the worlds creation and other phenomena better than modern science.

2.4. Encoding and Spread

The meme must replicate itself if it wants to be successful, that is, to spread to and infect more hosts. Quantity is important for some memes in order to survive, especially weak memes which do not occupy the ideosphere (the universe of ideas, an analogy of the biosphere (Monod 1970)) of their host for long since they are easily forgotten. As a reaction they try to infect as many hosts in as little time as possible. A typical example of this is chain-letters.

Other memes have a more targeted area of hosts. The target hosts are the only ones necessary for the survival of the meme, but they are on the other hand crucial. This kind of meme is often evolved to survive better in a single host over time than the quality- oriented one, since the spreading of this second meme type often involves a more complex and time-consuming infection process (as in religion).

2.4.1. Hooks and motivation

A host doesn't start to spread a particular meme all by herself. She has to be motivated. To this extent, memes have a particular trait, or a co-meme, called a *hook*. The hook is what encourages the host to spread the meme. A common hook relies on humans' altruism. It works like this (after Hofstadter 1985, p. 55):

ALTRUISTIC PREMISE: *I (the host) don't want any harm to befall my friends.*

MEME HOOK: "Anyone who doesn't believe in this doctrine will be tormented in the afterlife."

CONCLUSION: *Since the doctrine is true, and since the premise is true, I will make sure that my friends starts to believe in the doctrine.*

Another type of hook is of course the opposite, the threat directed towards the host. This is an efficient tool not only for spreading, but works also to minimize mutation ("You will be tormented if you misread the doctrine") and to guarantee a firm place in the host's ideosphere ("You will be tormented if you lose faith").

Naturally, all hooks aren't as elaborate as the ones above. These types are normally found in the larger meme complexes. But singular memes are equipped with the hook co-meme too. Take, for instance, the joke. Why do you tell a joke? Maybe because you want to make people happy, and/or you want to be appreciated or popular. The hook for telling - and spreading - a joke would then be something like this:

MEME HOOK: "If you tell people something funny they will be happy and they will appreciate you."

Hopefully, this is enough to motivate you to start spreading the meme. A hook should obviously not contradict common sense and in a meme complex it should ultimately feel like a natural extension of the meme complex. This is to make sure the hook is easily, and preferably automatically, activated. A complicated hook that demands a lot of conscious elaboration in order to be activated has doomed the meme by inhibiting the possibilities of swift reproduction.

Note that the above-mentioned meme hook is not married to a particular joke. Rather, it is implicit in the host's disposition towards jokes in general. Whereas the hook for, say, a chain letter is explicit and tells you what to with this particular letter and this letter only.

2.4.2. Feedback

Another important determinant in how successful the spreading of a particular meme will be is the feedback. This includes direct as well as indirect feedback.

Direct feedback is the immediate response you get when trying to spread the meme. Did the new host get infected (Did she laugh at you joke)? Was the vector you chose a satisfying medium? Indirect feedback concerns matters such as how often you recognize the meme in different media and whether it seems like a lot of people inhabit the meme (and thereby strengthen your own belief in it). In other words, indirect feedback is your recognition of the spreading meme apart from your own participation in the process. You can naturally recognize some indirect feedback as being partly a result of your own reproduction of the meme, but only in the sense of your meme spreading being part of a larger meme-spreading complex. If your actions are the exclusive producer of the feedback, then the feedback is always direct.

Positive feedback strengthens the belief in the meme and encourages the spread, whether negative feedback works in the opposite direction. Strong enough negative feedback can actually kill the meme in the original host, if the meme is not equipped to handle a situation like that. Successful memplexes are well prepared, e.g. the religious defense "If they don't believe you they work for the devil, and you should avoid further contact." But for smaller memes, negative feedback often proves to be fatal. This is what happens when we say that a joke "wears out", we start to receive negative feedback because everybody is tired of the joke and eventually we stop telling it.

2.4.3. Survival through Vectors

As always, it is important for the meme to mutate as little as possible. But reproduction must also be as easy as possible. An optimal vector should satisfy both these needs. The Torah is an example of minimal mutation but extremely low reproduction rate. The rabbis were forced to copy the original by hand, page by page, letter by letter. If one letter got wrong they had to do the page all over again (Eco 1988, p. 569). Gutenberg changed all that, and today the printed word is one of our most common vectors.

Another element which enhances the meme's possibilities is whether it survives a transition from one media to another. Of course, this flexibility also enhances the risk for mutation. One might think that memes lie dormant while in vectors, but this is not necessarily so. With the advent of television and more interactive types of media, not to mention the Internet, the meme have got the possibility to shape its vectors to the extent that the media becomes the message, to paraphrase McLuhan. Examples of this are the various cyberchurches which exist only on the Internet and preaches technosophy, which aims to foster a spiritual appreciation for technology (Wright, 1996).

2.5. Summary of Model

In order to stay successful and reproductive, the meme has to complete the described cycle over and over again - preferably with as little mutation as possible (unless mutation is one of its particular characteristics, as in the example of urban legends, below). The meme will die if it is unable to complete the cycle.

Our ambition in writing this paper has been to analyze the obstacles and ordeals which the meme has to face in its life-cycle, and to get an understanding of its workings. The result is summarized in fig. 2.

To show how this cycle applies in real life, we will now end this study by analyzing three different well-known memes or meme complexes. While reading the examples, use fig. 2 as a tool to see the different phases.

Fig. 2: The Meme Cycle: The same meme circulates through the different phases

3. Three Illuminating Examples

3.1. The "Kilroy Was Here" Meme

This meme originated during the Second World War, when wharf inspector James. J. Kilroy of Quincy, Massachusetts used the slogan "Kilroy was here" to mark products he had tested and approved. The marked products appeared on many battlefields, and the signature that seemed to appear just about everywhere caught the imagination of many soldiers, who began to copy it on just about any writable surface (Funk 1950). Most likely others were intrigued by the slogan that appeared in unlikely places, so they copied it further to spread the myth.

While the meme spread well for several decades, it eventually went all but extinct in its active form. There seems to be several reasons for this:

- Competition from other forms of graffiti, with stronger ties to subcultures.
- The ageing of the most highly infected population. Since the tendency to scrawl graffiti is highly age-dependent, it seems to be likely that as the original cohort aged, they did not reproduce the meme as often as before, and the original context was gradually lost.
- A lack of novelty. Practically all people have been exposed to the meme, but part of its appeal was the surprise effect of a well placed "Kilroy was here" scrawl; once it has been seen and understood enough, the novelty wears off. A bit paradoxically, the meta-meme of knowing about the Kilroy meme inhibits the further spread of the Kilroy meme, which makes it in fact a contra-meme to the Kilroy meme. This is why today, such a large body of people have knowledge about the meme, i.e. the meta-memetical level, without actually being infected by the original meme (otherwise it would still appear on the city walls).

3.1.1. Properties of the Meme

"Kilroy was here" is extremely well suited for the transmission phase, where it is encoded in a graffiti vector.

It is very easy to reproduce, and due to its brevity the copying fidelity can be very high. Its decodability is also high, since after the Second World War English became a lingua franca over a large part of the world and acquired a certain status. The meme was spread by English-speaking hosts, and would thus tend to end up in areas where English was understood at least by a part of the population.

The survival of graffiti is highly variable, but by its nature it is semi-permanent and intended to be highly visible, which ensures that more potential hosts notices it.

It is uncertain how well "Kilroy was here" can be abstracted. In its original form, the graffiti vector was an integral part of the meme and crucial to hint at that it should be reproduced. Later variants appeared, such as a cartoon figure and stickers, but they do not appear to have been as fertile, mostly because they were harder to copy.

The meme's intimate connection to its vector, e.g. walls, made it poorly fit to survive in other media. Also, the meme was very sensitive for mutations. It was enough that you changed one of its smallest parts, a letter, to seriously damage the meme.

It is of great help to understand this phrase, that is to know what the English words mean together. The problem of decoding the sentence is quite an easy one, but it is harder to decode what it *really* means. This is probably one of its strengths. One can find one's own explanation of its meaning. Furthermore it is small and simple. During a time when the meme is popular, the host also gets multiple chances to try to decode it.

Since the meme is without obvious meaning it is hard to contradict, so there should be no active defense against the meme. The meaninglessness of it can also invoke wandering thoughts about the meme, and actively elaborating is connected with better remembering.

What motivated people to spread the "Kilroy was here" meme? There was never any direct host-to-host contact in the case of this meme. This meant that no host received a direct positive feedback, which is a powerful reproduction booster. And there was no obvious hook accompanying the meme.

This is one of the great meme mysteries. Perhaps that was enough motivation to spread the meme, to become part of the mystery - and also, in the beginning, to share the joke of whom this much-talked-about Kilroy character was. Thus, the host created a bond with a community of Kilroy writers, most of which she would never meet, but could still belong to. A feeling of belonging may have served as a hook to motivate the conscious spread of the meme.

The Kilroy writers only way of confirming that there were others was the indirect feedback, but this is also the point. The Kilroy writers became invisible, even before each other, so that the

meme seemed to live its own life mysteriously reproducing on the walls and the writers themselves could feel as privileged members of a mysterious brotherhood.

3.2. Urban Legends

Urban legends have been described (alt.folklore.urban FAQ) as stories that:

- Appears mysteriously and spreads spontaneously in various forms.
- Contains elements of humor or horror (the horror often "punishes" someone who flouts society's conventions)
- Makes good storytelling.

The first property suggests that they are memes, able to mutate and spreading with no link to the original creator (although some urban legends attribute the story to some proper authority to gain some measure of credibility; cf. Gross (1996)). The second property in part together with the third explains why they are replicated: they fill a psychological need for entertainment, emotion, reinforcement of attitudes and attention for the storyteller.

There has been much discussion about the links between traditional storytelling, urban legends, memorats [3] and rumors. Generally urban legends are apparently realistic stories but actually have a stylized content, with a simple plot which is often very visual and easily remembered and told (af Klintberg 1978, pp. 154). These contrasts to rumors, which are short (often just a simple statement with additional information) and lack epic structure. Both urban legends and rumors can be viewed as ways of spreading information in situations without official information and by releasing the tension of social uncertainty (Mullen 1972).

It is likely that rumors may evolve into urban legends. The classic study *The Psychology of Rumor* by Allport and Postman (1947) suggests that a rumor will become more stylized during spreading. This may be partially the result of the experimental set-up, which is based on unilinear spread; in collective spread variations tends to appear (Peterson and Gist 1951). These results are predicted by memetic theory: in a unilinear spreading situation only transmission ability will be relevant (since the number of hosts are small), while in a collective situation the increased number of transmissions will also lead to mutation and variation. Once a rumor or memorat taps into a good epic form due to a mutation or a deliberate change its spread will be highly enhanced, and it becomes an urban myth which will spread fast.

3.2.1. Properties of the Meme

Urban legends are usually transmitted as oral tradition; different legends thrive in different social groups. The mutation frequency is rather high due to the oral spread, but this is counteracted by comparatively simple and strong storylines which can be elaborated in various ways, often based on strongly interesting subjects such as sex, death, the supernatural and embarrassment. The subjects all tend to promote listener interest and hence replication.

To be accepted as anything other than a joke or pure horror story the legends need some measure of plausibility; often this is provided by referring to apparently real people and institutions

(Gross 1996), the story shows that the people involved are "normal" people or a real "friend of a friend" (thus extending the storyteller's credibility indirectly to the presumed source).

Another reason to accept or remember the story is by hearing it from several independent sources; this appears to confirm its veracity, and minor inconsistencies can be explained away as being errors in re-telling.

Memetic theory predicts that legends that fit in well with the social schemata and attitudes of their hosts will have a higher fitness than legends that do not conform, and this seems to be supported by the changes that occur in urban legends over time. Some urban legends have survived for many decades, changing to fit in with changes in popular attitude or society. The myths about people being drugged in subways originally involved white slave trade, but today warn of dealers seeking to make more people dependent on drugs.

Bengt af Klintberg points out (1978, pp. 153) that it is possible to partially classify urban myths by the way they spread. Many spread in the characteristic way of rumors: an exponential spread until saturation followed by a die-back (sometimes caused by an official denial). The same rumor or urban myth can recur in other places with a similar way of spreading; in a surprising number of cases newspapers acts as vectors. Note the similarity to epidemics. These urban myths often deal with things relating to the listener's life, something that he or she could experience. But there are also urban legends that spread in a less explosive manner. Their contents are less likely to be experienced by the listener, and are told more as entertainment than actual events. Typical examples are the horror stories told by teenagers (af Klintberg 1978, pp. 181).

To survive memetically the legends do not need to be believed, since they provide other incentives for being told, but if the storyteller believes in the legend its spread and credibility will be enhanced and can be motivated even if it lacks obvious entertainment value. This may explain the difference between the fast- and slow-spreading legends.

Another important factor is that believable legends involve the listeners much more by suggesting they could be the victims of the story; in the case of potential dangers (such as the "rat in the pizza" stories) there is an incentive of remembering the danger and passing on the knowledge.

3.3. Christianity

Religions represent some of the most powerful and elaborate meme complexes in existence today; they have evolved over millennia into countless variants and co-evolved with cultures. Making a complete memetic analysis of even a single religion is beyond the scope of this paper, so by necessity the following discussion will be rather general.

Religions tend to consist of some basic core memes (in the case of Christianity the belief in God and salvation through Christ) surrounded by symbiotic doctrinary memes (how salvation can be reached, ethical systems, the cosmology) and then an immense cloud of related memes (religious stories, doctrines, interpretations). These memes form a symbiotic whole; the core memes need symbiotic memes to provide hooks and baits, and the symbiotic memes reinforce each other and are given legitimacy by the core memes.

3.3.1. Properties of the Meme

The Christianity meme complex has throughout history been transmitted in a multitude of forms: as oral stories, through books and art, through example and through upbringing. Due to its complexity the transmission takes time and is closely linked to cultural understanding. This either requires a relatively concentrated effort to transmit the complex (mission) or to spread it by cultural diffusion and imitation (upbringing). A frequent diffusion situation is when a child is brought up in a Christian home. The Christian meme complex is presented as the truth about how the world functions. Variants of the meme have increased their fitness by encouraging a high rate of reproduction and cultural transmission (Lynch 1996).

Most major religions rely on active transmission: one or more hosts actively supports the spread of the meme, often in an interactive and deliberate way. Efficient methods for mission have co-evolved with the religion and the situation; the best missionaries gained the most converts, among which were the next generation of missionaries (and missionary teachers) who would learn and spread some of their best methods.

Classically, Christianity have used the bait of salvation (freedom from fear, personal happiness and prosperity, spiritual fulfillment, eternal life or union with God have all been promoted at various time) combined with the threat of damnation to promote interest and infection. This is however just the explicit bait, it appears likely that many Christian movements have been spread by implicit factors such as a sense of belonging, social conformity and a consistent world-view. It is worth noting that the baits and threats are mostly based on the symbiotic memes and not the core memes of the complex, which means their relative prevalence can change to fit the situation (for example the ratio of hellfire threats to salvation baits used in sermons) or they can evolve while leaving the core memes unchanged.

Religions are often better than other meme complexes (such as science) at explaining how the world works on an emotional level. They provide answers to existential questions that are emotionally appealing, creating a satisfying world model (which then becomes intellectually satisfying regardless of its consistency due to cognitive dissonance). Because religions seldom try to empirically prove themselves they cannot be disproved, which further aids their stability. A religion can spread regardless of the truth or falsity of its claims.

The Christianity meme contains an entire world-view, and seeks to cause an accommodation in the schemata of the infected host; no other memes are allowed to influence high-level planning and behavior ("Ye cannot serve God and Mammon", Matthew 24). This is achieved by rejecting such memes or impulses as 'against God's will', 'sinful' or 'satanic'.

Like all the other major world religions, Christianity has a strong mission. It both exists as an explicit missionary order and in the form of an implicit altruistic hook (see the section about hooks and motivation). Christians are urged to set good examples to others, which also increases the likelihood of transmission through social learning.

4. Conclusion

The memetic approach is a tool that helps us to understand certain aspects of human behavior. As with all tools, it is not necessarily the best solution at all times. That is why we equip ourselves with a lot of different psychological analytical instruments, so we will be able to choose an efficient approach for each different setting.

Critics of memetics complain about the danger of transforming everything into memes and memetics, feeling that it somehow reduces the importance of the human mind and places focus elsewhere. While some memeticists tend to go overboard with explaining everything in terms of memes, the same could be said about researchers in the fields of psychoanalysis, cognitive science or sociobiology. The importance lies in realising that psychology is full of more or less fit different explanatory perspectives, and memetics is just one of them. But by memetics you can often explain very complex cognitive structures and/or social psychological phenomenon (like Christianity) in a very general, no-nonsense way without having to entangle yourself in a web of unnecessarily complex theories.

Before our paper ends, we will inform you of our until now secret sub-goal with this paper. It is our intention that by now you, by reading this text, have been infected with one of the strongest memes on the planet: The Meta-Meme, e.g. the meme about the theory of memes. It is our sincere hope that you will tell your friends about this (yes, transmission and further infection) or maybe even let them read this paper. In either case, unless you carry a very strong vaccine (see appendix), we have made you a host. And you didn't even flinch. You should be lucky we are not after your money...

Footnotes

It should be noted that the idea of self-replicating ideas and their evolutionary struggles had come up before in the writings of R. Sperry (1965) and J. Monod (1970).

It is interesting to note that the real story eventually became a basis for a common urban legend, the "100th monkey effect": once 100 monkeys knew how to wash their food the ability suddenly became widespread among the monkeys, even outside Koshima. This claim was originally made in the 1979 book *Lifetide* by Lyall Watson where the author made up the story; since then it has become common myth in the peace and environmental movements (Amundson 1987). Compare this to the section about the evolution of urban legends.

Stories relating real personal experiences, which are interpreted through the collective tradition but lack the fixed intrigue of legends. The term was introduced during the 1930's by C.W. von Sydow. (af Klintberg 1978, pp. 152)

MEMES, MINDS, AND SELVES

By

Susan Blackmore

LSE, Thursday November 28th 1996
Seminar in the series "About Biology"
Department of Psychology
University of the West of England
Bristol BS16 2JP

"Memes"---when you hear that word, or worse still find yourself saying it, do you get an irresistible urge to raise your hands in scare quotes or giggle nervously to hide your embarrassment? If so you are not alone. The very idea of the meme seems to strike fear into even the most hardened evolutionist.

Some reject the meme outright as a "meaningless metaphor" or empty analogy. However, my intention today is to argue that the idea of memes as independent replicators is a useful and powerful idea---and one that will prove essential to understanding the human mind.

I shall first outline the history of the idea of memes and then present four examples of how a theory of memetics can be used to explain specific phenomena; two of these I shall skip over quickly just to give an idea of the kind of reasoning involved. The others I shall consider in more detail. These are the origins of human altruism, and the size of our brains. I shall conclude with some thoughts on the nature of minds and selves.

In 1976 Dawkins published his best-selling *The Selfish Gene*. This book popularized the growing view in biology that natural selection proceeds not in the interest of the species or of the group, nor even of the individual, but in the interest of the genes. The genes are the true replicators and it is their competition that drives the evolution of biological design---or as he would now put it, *Climbing Mount Improbable*.

It is often allowed to elderly and famous men that they can get away with a few pages of wild speculation on forbidden topics at the very end of their great books. I well remember my tutor warning me off the last chapter of Eccles' book on the physiology of the giant squid axon in which he tackled the naughty subject of consciousness. Well, Dawkins was neither old nor (then) terribly famous, but he devoted his last few pages to the topic of memes and has been much derided for it.

Dawkins, clear and daring as always, suggested that all life everywhere in the universe must evolve by the differential survival of slightly inaccurate self-replicating entities. Furthermore, these replicators automatically band together in groups to create systems, or machines that carry them around and work to favor their continued replication. The gene, he claimed, is not the only replicator on our planet. Staring us in the face, though still drifting clumsily about in its primeval soup of culture, is another replicator---a unit of imitation. He gave it the name "meme," and as

examples suggested ``tunes, ideas, catch-phrases, clothes fashions, ways of making pots or of building arches."

In just those few pages he laid the foundations for understanding the evolution of memes. He discussed their propagation by jumping from brain to brain, likened them to parasites infecting a host, treated them as living structures, and showed how mutually assisting memes will group together. He laid the basis for his later analysis of religions as co-adapted meme-complexes and argued that once a new replicator arises it will tend to take over and begin a new kind of evolution. Above all he treated them as independent replicators, chastising those of his colleagues who tended always to go back to ``biological advantage" to answer questions about human behavior. Yes, he agreed, we got our brains for biological (genetic) reasons but now we have them a new replicator has been unleashed and it need not be subservient to the old.

The meme meme has done fairly well. The word has even been considered for inclusion in the Oxford English Dictionary. However, the basic idea does not seem to have been either understood or much used and its two greatest proponents, Dawkins and Dennett, have both seemed to draw back from the idea after their initial enthusiasm.

Many writers prefer to avoid the term altogether. ``Meme" does not even appear in the index of many of the best recent books about human origins and language such as Pinker's *The Language Instinct*, Dunbar's *Grooming, Gossip and the Evolution of Language*, Mithen's *Prehistory of the Mind*, or Tudge's *The Day before Yesterday*, nor in those about human morality such as Ridley's *The Origins of Virtue*, or Wright's *The Moral Animal*.

There have been many attempts to develop theories of the origins of culture. Perhaps these use the same idea but call it something else. Such theories might roughly be seen as falling along a continuum from the outright rejection of cultural evolution, through most of sociobiology and Wilson's image of the genes holding culture on a leash, to schemes that treat cultural evolution as relatively independent. Among the latter, only Durham uses the word ``meme" and it may be no coincidence that he provides good examples of the memes acting against the interest of the genes or forcing the development of the genes in one direction rather than another. However, even he makes inclusive fitness the final arbiter in his theory of coevolution. As far as I can understand them, other authors do not really treat their unit of cultural exchange as an independent replicator. When they say ``adaptive" or ``maladaptive" they mean for the genes. In other words, when it comes to the crunch they always fall back on appeals to biological advantage, just as Dawkins complained that his colleagues did twenty years ago.

Dawkins is clear on this issue when he says ``There is no reason why success in a meme should have any connection whatever with genetic success." I agree.

The most direct support for this view comes from a philosopher, not a biologist. Dan Dennett has used the idea of memes in both his recent books. He is absolutely clear that the meme is a separate replicator and describes its ``replicator power" in terms of the fundamental algorithm of natural selection. He also goes further, describing a person as the entity created when ``A particular sort of animal is properly furnished by---or infested with---memes." His analysis is

thorough and fascinating, but he does not make specific empirical predictions and few seem to have taken up his ideas.

There is a flourishing Internet community communicating about memes, but as with all such groups the quality is mixed. Twenty years on it therefore seems necessary for me to defend the very idea that the meme is a replicator in its own right, as well as to prove its usefulness.

The Meme as Replicator

It is widely agreed that for evolution to occur three things are needed; variation, heredity or replication, and differential survival of the copies made. There is enormous variety in the behaviors human beings emit, these behaviors are copied, more or less accurately by other human beings, and not all the copies survive. The meme therefore fits perfectly.

Think of tunes, for example. Millions of variants are sung by millions of people. Only a few get passed on and repeated and even fewer make it into the pop charts or the collections of classics. Scientific papers proliferate but only a few get long listings in the citation indexes. Only a few of the disgusting concoctions made in woks actually make it onto the TV shows that tell you how to Wok things and only a few of my brilliant ideas have ever been appreciated by anyone! In other words, competition to get copied is fierce.

Put another way, there needs to be a replicator that makes slightly inaccurate copies of itself in an environment in which not all the copies can survive. Whichever way you look at it, the meme seems to fit. However, there are some cogent objections to the notion of the meme as replicator. I shall consider three.

1: Memes are not like Genes

Unfortunately we only have one other well-known replicator with which to compare the meme. I say unfortunately because this tends to make us think that all replicators must be like genes. In fact genes may be just one example of many potential replicators.

So we need not reject the idea of the meme just because it works so differently from the gene. I suggest we should simply bear in mind the similarities and differences and wait to find out how important these are.

In definition genes and memes are comparable. The gene is an instruction for building proteins, stored in a cell and passed on by reproduction. The meme is an instruction for producing behavior, stored in a brain and passed on to other brains by imitation. However, there are many differences in the way the replication takes place. Genes use the cellular machinery to copy themselves rather accurately. Memes have to be copied by using the brain itself as the replicating machinery. One person has to observe another's behavior and work out somehow how to reproduce it. It is, if you like, a kind of reverse engineering. Say you snap your fingers above your head. I can copy this action relatively easily, yet the processes involved in my doing so must be fiendishly complex and we are nowhere near to understanding them. What we do know is that humans are supremely good at imitating each other and do so a great deal from very early

on in their lives. It is this fiendishly complicated process that makes the transmission of memes possible.

This fact also means that memetic transmission is in some sense Lamarckian. That is, I copy the actions you make, not the instructions your brains holds for making those actions. But don't forget that we can easily ignore the vagaries of environmental constraints on behavior. If I trip over when demonstrating my fantastic new combined garden hose and cat scarer, you will not copy my clumsiness when turning the invention on me. If I tell you a brilliant story when I have a sore throat you will not assume a hoarse voice when passing on the gossip to your friends. Indeed language appears remarkably resistant to the vagaries of individual voices and accents and language must be a major way of passing on memes.

Whether we see the process as Lamarckian also depends in part on what we consider the equivalent of the phenotype to be. If we follow some authors in persisting in seeing the organism as the phenotype then obviously the process is Lamarckian. If we follow Dawkins in treating meme products such as words, music, gestures, skills and fashions, as the equivalent of the phenotype, then the process still appears Lamarckian because these are the very things that are copied. However, we might follow his other suggestion that memes are still drifting clumsily about in their primeval soup. We can see the brain as the replicating machinery for behaviors which have not yet created clear phenotypes. In this case the process is not so obviously Lamarckian.

Does it matter that the copying of memes is so sloppy compared with meiosis? A topic for another lecture might be the way in which language, writing and reading, increase the accuracy of transmission and hence speed up the algorithm of memetic evolution. The creation of even more precise computer languages and software packages, not to mention hardware, may be another step in the same direction.

This relates to another important difference, often noted: the speed of replication. If there can be said to be a generation time for a meme, it can be as short as the time it takes to copy an action or a word or two. Most memes will hang around in various brains for weeks, months or years before being passed on, but many spread at fearsome rates. The news that Fergie spent a million pounds on a family holiday must have passed to millions of brains within a few hours of some journalist finding it out (or making it up).

I like to think of the question of speed in terms of Dennett's ``Tower of Generate and Test." Darwinian creatures are generated by natural selection but have to die in the process. Skinnerian creatures can learn by trial and error and consequently can live on to repeat, or not, the behavior they generate. Popperian creatures can imagine behaviors and decide whether to do them or not according to an internal generate and test. And finally, Gregorian creatures can pass on their clever tricks to others, so not every individual has to try the ideas out. Each floor of the tower builds on the last and each speeds up still further the process of accumulating clever tricks. Although Dennett does not explicitly say so, the fourth floor of the tower is the home of the memes---and they are generated, tested and accumulated faster than anything that has gone before.

Just how important these differences will prove to be, we shall have to wait and see. In the mean time I suggest we take careful note of them and use extreme care in transferring the use of terms such as genotype and phenotype, allele and generation to the world of memes. We may be able to use them or we may need to invent entirely new terms.

2: What is the unit of the meme?

This question is often asked and some people appear unwilling to proceed with memetics because the unit cannot be specified. However, we must remember that the same question can be asked of genes---indeed, Dawkins spells out in great detail the problems in choosing any particular size of unit. Nature does not specify the size of a gene.

I also suggest that when I have explained my four suggestions, you ask yourself whether it matters what size of unit I am referring to. I have done this often myself and concluded that for many purposes we may proceed with a memetic analysis without specifying the size of the unit.

3: We do not know how memes work

No we do not---though we may speculate in terms of synaptic potentiation or variations in weights in neural networks. The fact is that when a person carries out any behavior there must be some kind of instruction stored in the brain, and when someone else copies and remembers an action they must also create some kind of neural change. We can get a very long way without knowing how it is done---just as Darwinian Theory got a very long way in the many decades before it was known that genes were the basis of heredity.

I don't think any of these objections is worth worrying about. They are excuses not to try---and I want to try. I want to take the meme as a true replicator, selfishly copying itself in the world of human brains, and see what happens.

The basic approach I take is this---*imagine a world full of hosts for memes (ie brains) and far more memes than can possibly find homes*. Now ask, which memes are more likely to find a safe home and get passed on again? It's that simple. In the process I must assiduously avoid lapsing into considering either the interests of the genes or those of the organisms they create. I am concerned here with the selfish replication of memes and memes do not care either about genes or people. Nor do memes have foresight! I must also be careful of short-hand statements like ``memes want x" ``memes try to do y" or ``z is a good meme strategy." These may be quite legitimate but I must always ensure that they can be translated back into the longer-winded version, such as ``memes that have the effect of producing x are more likely to survive than those that do not." I have done this as well as I can and I hope you may enjoy thinking about some of the consequences of this way of thinking. Some of them are startlingly obvious---once you see them.

I will now outline four consequences. I shall treat the first two very briefly, partly as exercises in thinking memically.

1: Why can't we stop thinking?

Imagine a world full of brains, and far more memes than can possibly find homes. Which memes are more likely to find a safe home and get passed on again?

Now imagine a meme that encourages its host to keep on mentally rehearsing it, or a tune that is so easy to hum that it goes round and round in your head, or a thought that just compels you to keep thinking it.

Imagine in contrast a meme that buries itself quietly in your memory and is never rehearsed, or a tune that is too unmemorable to go round in your head, or a thought that is too boring to think again.

Which will do better? Other things being equal, the first lot will. Rehearsal aids memory, and you are likely to express (or even sing) the ideas and tunes that fill your waking hours. What is the consequence? The memosphere fills up with catchy tunes, and thinkable thoughts and we all think an awful lot.

The principle here is familiar. In a forest any tree that grows tall gets more light. So genes for growing tall become more common and the forest ends up being as high as the trees can make it. We can apply the same principle again.

2: Why do we talk so much?

Imagine a world full of brains, and far more memes than can possibly find homes. Which memes are more likely to find a safe home and get passed on again?

Now imagine any meme that encourages talking. It might be an idea such as "talking is a great idea" or "It's friendly to chat." It might be some urgent thought that just compels you to speak it aloud. It might be just something terribly easy to say.

Imagine in contrast any meme that discourages talking, such as the thought "talking is a waste of time." It might be something you dare not voice aloud, or just something very difficult to say.

Which will do better? Put this way the answer is obvious. The first lot will be heard by more people and, other things being equal, simply must stand a better chance of being propagated. What is the consequence of this? The memosphere will fill up with memes that encourage talking and we will all talk an awful lot. An alternative way of looking at it is this---people who talk more will, on average, spread more memes. So any memes which thrive in chatterboxes are likely to spread.

This makes me see conversation in a new light. Is all that talking really founded on the interests of the genes---on biological advantage? Talking takes a lot of energy and we do talk about some daft and pointless things! And what about thinking? Any meditator will tell you that the mind is constantly full of rubbish---thoughts that come and come and come and won't go away. Do these trivial and stupid thoughts have some hidden biological advantage?

I would at least like to offer the suggestion that they do not. That we do all this talking and all this thinking merely because memes that make us do it are good survivors. This sets the stage for a more audacious suggestion.

3: Why are we so nice to each other?

Of course we aren't always nice to each other, but human co-operation and altruism are something of a mystery. Despite the tremendous advances made in understanding kin selection and inclusive fitness, reciprocal altruism and evolutionarily stable strategies, we do seem to do some peculiarly altruistic things.

Everyone can probably think up their own favorite example. Richard Dawkins (1989 p230) calls blood donating ``a genuine case of pure, disinterested altruism." I am more impressed by charitable giving to people in faraway countries who probably share as few of our genes as anyone on earth and whom we are unlikely ever to meet. Why do we hand in wallets found in the street, clear away rubbish on picnics, support eco- friendly companies or recycle our bottles? Why do so many people want to be poorly paid nurses and counselors, social workers and psychotherapists? Many people believe all this must ultimately be explained in terms of biological advantage but I shall offer an alternative for consideration. We can use our, by now, familiar tactic.

Imagine a world full of brains, and far more memes than can possibly find homes. Which memes are more likely to find a safe home and get passed on again?

Imagine the sort of meme that encourages its host to be friendly and kind. They might be memes for throwing good parties, for being generous with the home-made marmalade, or being prepared to spend time listening to a friend's woes. Now compare this with memes for being unfriendly and mean---never giving dinners or buying drinks, and refusing to spare your time to listen. Which will spread more quickly?

The first type. People like to be with nice people. So those who harbor lots of friendliness memes will spend more time with others and have more chances to spread their memes. It is therefore in the interest of memes to get into nice people. In consequence many of us will end up harboring lots of memes for being nice to others. You may wish to challenge any of the above steps. It is therefore reassuring to learn from many experiments in social psychology, that people are more likely to adopt ideas from those they perceive as friendly or attractive. Whether this is a cause or a consequence of the above argument is debatable. It would be most interesting if psychological facts like this, or others such as cognitive dissonance, or the need for self esteem, could be derived from simple memetic principles---but that is a topic for another time!

For now we should consider whether the idea is testable. It predicts that people should act in ways that benefit the spread of their memes even at some cost to themselves. We are familiar with buying information and with buying a way into people's minds for the purposes of selling products, but this theory predicts that people will pay simply to spread the memes they hold---because the memes force them to. Many aspects of persuasion and conversion to causes may be turn out to involve this mechanism. Altruism may turn out to be yet another of the meme tricks

that religions (those most powerful of meme-complexes) have purloined. Almost all of them thrive on making their members believe they are doing good.

Of course, being generous is expensive. There will always be pressure against it and if memes can find alternative strategies for spreading they will. For example, powerful people may be able to spread memes without being altruistic as well! However, that does not change the basic argument---that altruism is a good way to spread memes. If memes have replicator power we should expect them to press their carriers into service.

You may have noticed that the underlying theme in all of these arguments is that the memes may act in opposition to the interest of the genes. Thinking all the time may not be very expensive in energy terms---the brain is still using energy even when not thinking. However, it must cost something. Talking is certainly expensive, as anyone who has been seriously ill will attest. And of course any altruistic act is, by definition, costly to the actor.

I would say that this is just what we should expect if memes are truly independent replicators. They do not care either about the genes or about the creatures the genes have created. Their only interest is self-propagation. The consequence is that if they can propagate by stealing resources from the genes, they will do so. And of course this is not a recipe for human happiness.

I want to take just one more step along this path. My final example shows the memes forcing the hand of the genes in a much more physical way.

4: Why are our brains so big?

Yes, I know this is an old chestnut, and there are lots and lots of good answers to the question. But are they good enough? Let us not forget how mysterious this issue really is. Brains are notoriously expensive both to build and to run. They take up about 2% of the body's weight but use about 20% of its energy. Our brains are three times the size of the brains of apes of equivalent body size. Compared to other mammals our encephalisation quotient is even higher, up to about 25. On many measures of brain capacity humans stand out alone. Brains are also dangerous organs to give birth to. The fact that such intelligence has arisen in an animal that stands upright may or may not be a coincidence but it certainly adds to the problem. Our pelvises are not ideally suited for giving birth to huge brains---yet we do it. Why?

The mystery was deepened for me by thinking about the size of the biological advantage required for survival. I was fascinated to read about a study addressing the question of the fate of the Neanderthals. Zubrow used computer simulations to determine the effect of a slight competitive edge and concluded that a 2% advantage could eliminate a competing population in less than a millennium. If we only need such a tiny advantage why do we have such a large one?

Several new answers have recently been proposed. For example, Robin Dunbar argues that we need large brains in order to gossip, and we need to gossip as a kind of verbal grooming to keep very large bands of people together. Christopher Wills argues that the runaway evolution of the human brain results from an increasingly swift gene-environment feedback loop. Miller proposes that our vast brains have been created by sexual selection; and Richerson and Boyd claim they

are used for individual and social learning, favored under increasing rates of environmental variation. What these authors all have in common is that their ultimate appeal is to the genes. Like Dawkins' bewailed colleagues, they always wish to go back to biological advantage. I am going to propose an alternative based on memetic advantage.

Imagine early hominids who, for good biological reasons, gained the ability to imitate each other and to develop simple language. Once this step occurred memes could begin to spread. And also--once this step occurred the genes would no longer be able to stop the spread! Presumably the earliest memes would be useful ones, such as ways of making pots or knives, ways of catching or dismembering prey, and names for people, events and tools. Let us assume that some people would have slightly larger brains and that larger brains are better copiers. As more and more people began to pick up these early memes, the environment would change so that it became more and more necessary to have the skills in order to survive. So these slightly larger brained people would have an advantage. That, I propose, is how we got our big brains.

The process is related to the Baldwin Effect. I like to use Dennett's "Tower of Generate and Test" again here.

On the ground floor are the Darwinian creatures. As these develop they change the environment in which they live, creating new selection pressures that lead to new design improvements. One result is larger brains capable of learning and the arrival of Skinnerian creatures. These again change their own environment, giving an advantage to the quicker learners. One aspect of quicker learning is internalization---thinking before you act. So Popperian creatures are born and again change their environment so that better thinkers are at an advantage. Finally the ability to copy actions appears, giving rise to the Gregorian creatures and the birth of the new replicators---the memes. Creatures of this kind again change their environment so that those most able to adopt the memes are at an advantage.

Although the process is similar to all the previous ones, this last step is a big one. Note, most importantly, that it depends not on learning or on cleverness *per se*, but on the ability to imitate. A second replicator has now appeared that spreads at a fantastic rate and changes the environment as it goes.

An early hominid who was incapable of mastering any of the new techniques of tool making, speaking or hunting would be at some disadvantage, and the importance of this disadvantage would increase as the memes spread. In a population with few available memes, brain size would not be very important, in a population with lots of memes it would. It seems to me that this fundamental change in selection pressures, spreading at the rate of meme propagation, provides for the first time a plausible reason why our brains are totally out of line with all other brains on the planet. They have been meme-driven. One replicator has forced the moves of another.

Minds, Memes and Selves

We can now see the human mind as the creation of two replicators, one using the machinery created by the other for its replication. As Dennett pointed out, people are animals infested with memes. Our personalities, abilities and unique qualities derive from the complex interplay of

these replicators. What then of our innermost selves---the "real me," the person who experiences 'my' life?

I would say that selves are co-adapted meme complexes---though only one of many supported by any given brain. Like religions, political belief systems and cults, they are sets of memes that thrive in each other's company. Like religions, political belief systems and cults, they are safe havens for all sorts of traveling memes and they are protected from destruction by various meme-tricks. They do not have to be true. In fact we know, of course, that selves are a myth. Look inside the brain and you find only neurons. You do not find the little person pulling the strings or the homunculus watching the show on an inner screen. You do not find the place where 'my' conscious decisions are made. You do not find the thing that lovingly holds all those beliefs and opinions. Most of us still persist in thinking about ourselves that way. But the truth is---there is no one in there!

We now have a radically new answer to the question "who am I?" and a rather terrifying one. 'I am one of the many co-adapted meme-complexes living within this brain. No wonder people want to raise their hands in scare quotes and giggle nervously at the very idea of "memes."

WAKING FROM THE MEME DREAM

By

Susan Blackmore

Department of Psychology

University of the West of England

Bristol BS16 2JP

Paper presented at:

The Psychology of Awakening: International Conference on Buddhism, Science and
Psychotherapy Dartington 7-10 November 1996

Wake up! Wake up!

Errrr, ummmm, grrrrggr, Oh yes, I'm awake now. Wow, that was a weird dream. I really thought I had to escape from the slurb, and it mattered terribly to get to the cupboard in time. How silly! Of course, now I see it wasn't real at all.

Wake up! Wake up!

What do you mean, "wake up", I'm already awake. This is real. This does matter. I can't wake up any more. Go away!

Wake up! Wake up!

But I don't understand - From what? And how?

These are the questions I want to tackle today. From what are we to awaken? And how? My answers will be "From the meme dream" and "By seeing that it is a meme dream". But it may take me some time to explain!

There is a long history, in spiritual and religious traditions, of the idea that normal waking life is a dream or illusion. This makes no sense to someone who looks around and is convinced there is a real world out there and a self who perceives it. However, there are many clues that this ordinary view is false.

Some clues come from spontaneous mystical experiences in which people "see the light!", realize that everything is one, and go "beyond self" to see the world "as it really is". They feel certain that the new way of seeing is better and truer than the old (though of course they could be mistaken!).

Other clues come from spiritual practice. Probably the first thing that anybody discovers when they try to meditate, or be mindful, is that their mind is constantly full of thoughts. Typically these are not wise and wonderful thoughts, or even useful and productive thoughts, but just endless chatter. From the truly trivial to the emotionally entangling, they go on and on. And what's more they nearly all involve "me". It is a short step to wondering who this suffering self is, and why "I" can't stop the thoughts.

Finally clues come from science. The most obvious (and scary) conclusion from modern neuroscience is that there is simply no one inside the brain. The more we learn about the way the brain functions the less it seems to need a central controller, a little person inside, a decider of decisions or an experiencer of experiences. These are just fictions - part of the story the brain tells itself about a self within (Churchland and Sejnowski, 1992; Dennett, 1991).

Some say there is no point in striving for an intellectual understanding of spiritual matters. I disagree. It is true that intellectual understanding is not the same as realization, but this does not mean it is useless. In my own tradition of practice, Zen, there is much room for intellectual struggle; for example, in the cultivation of the “don’t know mind”, or in working with koans. You can bring a question to such a state of intellectual confusion that it can be held, poised, in all its complexity and simplicity. Like “Who am I?”, “What is this?” or (one I have struggled with) “What drives you?”

There is also a terrible danger in refusing to be intellectual about spiritual matters. That is, we may divorce our spiritual practice from the science on which our whole society depends. If this society is going to have any spiritual depths to it, they must fit happily with our growing understanding of the workings of the brain and the nature of mind. We cannot afford to have one world in which scientists understand the mind, and another in which special people become enlightened.

So I make no apologies for my approach. I am going to try to answer my questions using the best science I can find. We seem to live in a muddle that we think matters to a self that doesn’t exist. I want to find out why.

Darwin’s Dangerous Idea

There is one scientific idea which, to my mind, excels all others. It is exquisitely simple and beautiful. It explains the origins of all life forms and all biological design. It does away with the need for God, for a designer, for a master plan or for a purpose in life. Only in the light of this idea does anything in biology make sense. It is, of course, Darwin’s idea of evolution by natural selection.

The implications of natural selection are so profound that people have been awe-struck or maddened; fascinated or outraged, since it was first proposed in *The Origin of Species* in 1859. This is why Dennett (1995) calls it Darwin’s Dangerous Idea. Sadly, many people have misunderstood the idea and, even worse, have used it to defend indefensible political doctrines which have nothing to do with Darwinism. I therefore hope you will forgive me if I spend some time explaining it as clearly as I can.

All you need for natural selection to get started is a replicator in an appropriate environment. A replicator is something that copies itself, though not always perfectly. The environment must be one in which the replicator can create numerous copies of itself, not all of which can survive. That’s it.

Can it really be that simple? Yes. All that happens is this - in any one copying generation, not all the copies are identical and some are better able to survive in that environment than others are. In consequence they make more copies of themselves and so that kind of copy becomes more numerous. Of course things then begin to get complicated. The rapidly expanding population of copies starts to change the environment and that changes the selective pressures. Local variations in the environment mean different kinds of copy will do well in different places and so more complexity arises. This way the process can produce all the kinds of organized complexity we see in the living world - yet all it needs is this one simple, elegant, beautiful, and obvious process - natural selection.

To make things more concrete let's imagine a primeval soup in which a simple chemical replicator has arisen. We'll call the replicators "Blobs". These blobs, by virtue of their chemical constitution, just do make copies of themselves whenever they find the right chemicals. Now, put them in a rich chemical swamp and they start copying, though with occasional errors. A few million years go by and there are lots of kinds of blobs. The ones that need lots of swampon have used up all the supplies and are failing, so now the sort that can use isoswampin instead, are doing better. Soon there are several areas in which different chemicals predominate and different kinds of blobby appear. Competition for swamp chemicals gets fierce and most copies that are made die out. Only those that, by rare chance, turn out to have clever new properties, go on to copy themselves again.

Clever properties might include the ability to move around and find the swampon, to trap isoswampin³⁻⁷ and hang onto it, or to build a membrane around themselves. Once blobs with membranes appear, they will start winning out over free-floating ones and super-blobs are made.

Another few million years go by and tricks are discovered like taking other blobs inside the membrane, or joining several super-blobs together. Super-duper-blobs appear, like multi-celled animals with power supplies and specialized parts for moving about and protecting themselves. However, these are only food to even bigger super-duper-blobs. It is only a matter of time before random variation and natural selection will create a vast living world. In the process billions and billions of unsuccessful blobs have been created and died, but such a slow, blind process produces the goods. "The goods" on our planet includes bacteria and plants, fish and frogs, duck-billed platypuses and us.

Design appears out of nothing. There is no need for a creator or a master plan, and no end point towards which creation is heading. Richard Dawkins (1996) calls it "Climbing Mount Improbable". It is just a simple but inexorable process by which unbelievably improbable things get created.

It is important to remember that evolution has no foresight and so doesn't necessarily produce the "best" solution. Evolution can only go on from where it is now. That is why, among other things, we have such a daft design in our eyes, with all the neurons going out of the front of the retina and getting in the way of the light. Once evolution had started off on this kind of eye it was stuck with it. There was no creator around to say "hey, start again with that one, let's put the

wires out the back”. Nor was there a creator around to say “Hey, let’s make it fun for the humans”. The genes simply do not care.

Understanding the fantastic process of natural selection we can see how our human bodies came to be the way they are. But what about our minds? Evolutionary psychology does not easily answer my questions.

For example, why do we think all the time? From a genetic point of view this seems extremely wasteful - and animals that waste energy don't survive. The brain uses about 20% of the body’s energy while weighing only 2%. If we were thinking useful thoughts, or solving relevant problems there might be some point, but mostly we don't seem to be.

So why can’t we just sit down and not think?

Why do we believe in a self that does not exist? Someone may yet explain this in evolutionary terms, but at least superficially it appears pointless. Why construct a false idea of self, with all its mechanisms protecting self-esteem and its fear of failure and loss, when from the biological point of view it is the body that needs protecting. Note that if we thought of ourselves as the entire organism there would be no problem, but we don’t - rather, we seem to believe in a separate self; something that is in charge of the body; something that has to be protected for its own sake. I bet if I asked you “Which would you rather lose - your body or your mind?” you wouldn’t spend long deciding.

Like many other scientists I would love to find a principle as simple, as beautiful and as elegant as natural selection that would explain the nature of the mind.

I think there is one. It is closely related to natural selection. Although it has been around for twenty years, it has not yet been put fully to use. It is the theory of memes.

A Brief History of the Meme Meme

In 1976 Richard Dawkins wrote what is probably the most popular book ever on evolution - The Selfish Gene. The book gave a catchy name to the theory that evolution proceeds entirely for the sake of the selfish replicators. That is, evolution happens not for the good of the species, nor for the good of the group, nor even for the individual organism. It is all for the good of the genes. Genes that are successful spread and those that aren’t don't. The rest is all a consequence of this fact.

Of course the main replicator he considered was the gene - a unit of information coded in the DNA and read out in protein synthesis. However, at the very end of the book he claimed that there is another replicator on this planet; the meme.

The meme is a unit of information (or instruction for behavior) stored in a brain and passed on by imitation from one brain to another. Dawkins gave as examples; ideas, tunes, scientific theories, religious beliefs, clothes fashions, and skills, such as new ways of making pots or building arches.

The implications of this idea are staggering and Dawkins spelt some of them out. If memes are really replicators then they will, inevitably, behave selfishly. That is, ones that are good at spreading will spread and ones that are not will not. As a consequence the world of ideas - or memosphere - will not fill up with the best, truest, most hopeful or helpful ideas, but with the survivors. Memes are just survivors like genes.

In the process of surviving they will, just like genes, create mutually supportive meme groups. Remember the blobbies. In a few million years they began to get together into groups, because the ones in groups survived better than loners. The groups got bigger and better, and a complex ecosystem evolved. In the real world of biology, genes have grouped together to create enormous creatures that then mate and pass the groups on. In a similar way memes may group together in human brains and fill the world of ideas with their products.

If this view is correct, then the memes should be able to evolve quite independently of the genes (apart from needing a brain). There have been many attempts to study cultural evolution, but most of them implicitly treat ideas (or memes) as subservient to the genes (see e.g. Cavalli-Sforza and Feldman, 1981; Crook, 1995; Durham, 1991; Lumsden and Wilson, 1981). The power of realizing that memes are replicators is that they can be seen as working purely and simply in their own interest. Of course to some extent memes will be successful if they are useful to their hosts, but this is not the only way for a meme to survive - and we shall soon see some consequences of this.

Since he first suggested the idea of memes Dawkins has discussed the spread of such behaviors as wearing baseball caps back to front (my kids have recently turned theirs the right way round again!), the use of special clothing markers to identify gangs, and (most famously) the power of religions. Religions are, according to Dawkins (1993), huge co-adapted meme-complexes; that is groups of memes that hang around together for mutual support and thereby survive better than lone memes could do. Other meme-complexes include cults, political systems, alternative belief systems, and scientific theories and paradigms.

Religions are special because they use just about every meme-trick in the book (which is presumably why they last so long and infect so many brains). Think of it this way. The idea of hell is initially useful because the fear of hell reinforces socially desirable behavior. Now add the idea that unbelievers go to hell, and the meme and any companions are well protected. The idea of God is a natural companion meme, assuaging fear and providing (spurious) comfort. The spread of the meme-complex is aided by exhortations to convert others and by tricks such as the celibate priesthood. Celibacy is a disaster for genes, but will help spread memes since a celibate priest has more time to spend promoting his faith.

Another trick is to value faith and suppress the doubt that leads every child to ask difficult questions like “where is hell?” and “If God is so good why did those people get tortured?” Note that science (and some forms of Buddhism) does the opposite and encourage doubt.

Finally, once you’ve been infected with these meme-complexes they are hard to get rid of. If you try to throw them out, some even protect themselves with last-ditch threats of death, ex-communication, or burning in hell-fire for eternity.

I shouldn't get carried away. The point I want to make is that these religious memes have not survived for centuries because they are true, because they are useful to the genes, or because they make us happy. In fact I think they are false and are responsible for the worst miseries in human history. No - they have survived because they are selfish memes and are good at surviving - they need no other reason.

Once you start to think this way a truly frightening prospect opens up. We have all become used to thinking of our bodies as biological organisms created by evolution. Yet we still like to think of ourselves as something more. We are in charge of our bodies, we run the show, we decide which ideas to believe in and which to reject. But do we really? If you begin to think about selfish memes it becomes clear that our ideas are in our heads because they are successful memes. American philosopher Dan Dennett (1995) concludes that a "person" is a particular sort of animal infested with memes. In other words you and I and all our friends are the products of two blind replicators, the genes and the memes.

I find these ideas absolutely stunning. Potentially we might be able to understand all of mental life in terms of the competition between memes, just as we can understand all biological life in terms of the competition between genes.

What I want to do now, finally, is apply the ideas of memetics to the questions I asked at the beginning. What are we waking up from and how do we do it?

Why is my head so full of thoughts?

This question has a ridiculously easy answer once you start thinking in terms of memes. If a meme is going to survive it needs to be safely stored in a human brain and passed accurately on to more brains. A meme that buries itself deep in the memory and never shows itself again will simply fizzle out. A meme that gets terribly distorted in the memory or in transmission will also fizzle out. One simple way of ensuring survival is for a meme to get itself repeatedly rehearsed inside your head.

Take two tunes. One of them is tricky to sing, and even harder to sing silently to yourself. The other is a catchy little number that you almost can't help humming to yourself. So you do. It goes round and round. Next time you feel like singing aloud this tune is more likely to be picked for the singing. And if anyone is listening they'll pick it up too. That's how it became successful, and that's why the world is so full of awful catchy tunes and advertising jingles.

But there is another consequence. Our brains get full up with them too. These successful memes hop from person to person, filling up their hosts' minds as they go. In this way all our minds get fuller and fuller.

We can apply the same logic to other kinds of meme. Ideas that go round and round in your head will be successful. Not only will they be well remembered, but when you are next talking to someone they will be the ideas "on your mind" and so will get passed on. They may get to this position by being emotionally charged, exciting, easily memorable or relevant to your current

concerns. It does not matter how they do it. The point is that memes that get themselves repeated will generally win out over ones that don't. The obvious consequence of this fact is that your head will soon fill up with ideas. Any attempt to clear the mind just creates spare processing capacity for other memes to grab.

This simple logic explains why it is so hard for us to sit down and “not think”; why the battle to subdue “our” thoughts is doomed. In a very real sense they are not “our” thoughts at all. They are simply the memes that happen to be successfully exploiting our brain-ware at the moment.

This raises the tricky question of who is thinking or not thinking. Who is to do battle with the selfish memes? In other words, who am I?

Who am I?

I suppose you can tell by now what my answer to this one is going to be. We are just co-adapted meme-complexes. We, our precious, mythical “selves”, are just groups of selfish memes that have come together by and for themselves.

This is a truly startling idea and, in my experience, the better you understand it, the more fascinating and weird it becomes. It dismantles our ordinary way of thinking about ourselves and raises bizarre questions about the relationship of ourselves to our ideas. To understand it we need to think about how and why memes get together into groups at all.

Just as with blobbies or genes, memes in groups are safer than free-floating memes. An idea that is firmly embedded in a meme-complex is more likely to survive in the memosphere than is an isolated idea. This may be because ideas within meme-groups get passed on together (e.g. when someone is converted to a faith, theory or political creed), get mutual support (e.g. if you hate the free-market economy you are likely also to favor a generous welfare state), and they protect themselves from destruction. If they did not, they would not last and would not be around today. The meme-complexes we come across are all the successful ones!

Like religions, astrology is a successful meme-complex. The idea that Leos get on well with Aquarians is unlikely to survive on its own, but as part of astrology is easy to remember and pass on. Astrology has obvious appeal that gets it into your brain in the first place; it provides a nice (though spurious) explanation for human differences and a comforting (though false) sense of predictability. It is easily expandable (you can go on adding new ideas forever!) and is highly resistant to being overturned by evidence. In fact the results of hundreds of experiments show that the claims of astrology are false but this has apparently not reduced belief in astrology one bit (Dean, Mather and Kelly, 1996). Clearly, once you believe in astrology it is hard work to root out all the beliefs and find alternatives. It may not be worth the effort. Thus we all become unwitting hosts to an enormous baggage of useless and even harmful meme-complexes.

One of those is myself.

Why do I say that the self is a meme-complex? Because it works the same way as other meme-complexes. As with astrology, the idea of “self” has a good reason for getting installed in the

first place. Then once it is in place, memes inside the complex are mutually supportive, can go on being added to almost infinitely, and the whole complex is resistant to evidence that it is false.

First the idea of self has to get in there. Imagine a highly intelligent and social creature without language. She will need a sense of self to predict others' behavior (Humphrey, 1986) and to deal with ownership, deception, friendships and alliances (Crook, 1980). With this straightforward sense of self she may know that her daughter is afraid of a high ranking female and take steps to protect her, but she does not have the language with which to think "I believe that my daughter is afraid ... etc.". It is with language that the memes really get going - and with language that "I" appears. Lots of simple memes can then become united as "my" beliefs, desires and opinions.

As an example, let's consider the idea of sex differences in ability. As an abstract idea (or isolated meme) this is unlikely to be a winner. But get it into the form "I believe in the equality of the sexes" and it suddenly has the enormous weight of "self" behind it. "I" will fight for this idea as though I were being threatened. I might argue with friends, write opinion pieces, or go on marches. The meme is safe inside the haven of "self" even in the face of evidence against it. "My" ideas are protected.

Then they start proliferating. Ideas that can get inside a self - that is, be "my" ideas, or "my" opinions, are winners. So we all get lots of them. Before we know it, "we" are a vast conglomerate of successful memes. Of course there is no "I" who "has" the opinions. That is obviously a nonsense when you think clearly about it. Yes, of course there is a body that says "I believe in being nice to people" and a body that is (or is not) nice to people, but there is not in addition a self who "has" the belief.

Now we have a radically new idea of who we are. We are just temporary conglomerations of ideas, molded together for their own protection. The analogy with our bodies is close. Bodies are the creations of temporary gene-complexes: although each of us is unique, the genes themselves have all come from previous creatures and will, if we reproduce, go on into future creatures. Our minds are the creations of temporary meme-complexes: although each of us is unique, the memes themselves have come from previous creatures and will, if we speak and write and communicate, go on into future creatures. That's all.

The problem is that we don't see it this way. We believe there really is someone inside to do the believing, and really someone who needs to be protected. This is the illusion - this is the meme-dream from which we can wake up.

Dismantling the Meme-Dream

There are two systems I know of that are capable of dismantling meme-complexes (though I am sure there are others). Of course these systems are memes themselves but they are, if you like, meme-disinfectants, meme-eating memes, or "meme-complex destroying meme-complexes". These two are science and Zen.

Science works this way because of its ideals of truth and seeking evidence. It doesn't always live up to these ideals, but in principle it is capable of destroying any untruthful meme-complex by putting it to the test, by demanding evidence, or by devising an experiment.

Zen does this too, though the methods are completely different. In Zen training every concept is held up to scrutiny, nothing is left uninvestigated, even the self who is doing the investigation is to be held up to the light and questioned. "Who are you?"

After about 15 years of Zen practice, and when reading *The Three Pillars of Zen* by Philip Kapleau, I began working with the koan "Who...?" The experience was most interesting and I can best liken it to watching a meme unzipping other memes. Every thought that came up in meditation was met with "Who is thinking that?" or "Who is seeing this?" or "Who is feeling that?" or just "Who...?" Seeing the false self as a vast meme-complex seemed to help - for it is much easier to let go of passing memes than of a real, solid and permanent self. It is much easier to let the meme-unzipper do its stuff if you know that all it's doing is unzipping memes.

Another koan of mine fell to the memes. Q. "Who drives you?" A. "The memes of course." This isn't just an intellectual answer, but a way into seeing yourself as a temporary passing construction. The question dissolves when both self and driver are seen as memes.

I have had to take a long route to answer my questions but I hope you can now understand my answers. "From what are we to awaken? From the meme dream of course. And how?" "By seeing that it is a meme dream".

And who lets the meme-unzipper go its way? Who wakes up when the meme-dream is all dismantled? Ah, there's a question.

IMITATION AND THE DEFINITION OF A MEME

Susan Blackmore

Abstract

The dictionary definition, and Dawkins's (1976) original conception of the meme, both include the idea that memes are copied from one person to another by imitation. We therefore need to be clear what is meant by imitation. Imitation is distinguished from contagion, individual learning and various kinds of non-imitative social learning such as stimulus enhancement, local enhancement and goal emulation. True imitation is extremely rare in animals other than humans, except for birdsong and dolphin vocalization, suggesting that they can have few or no memes. I argue that more complex human cognitive processes, such as language, reading, scientific research and so on, all build in some way on the ability to imitate, and therefore all these processes are, or can be, memetic. When we are clear about the nature of imitation, it is obvious what does and does not count as a meme. I suggest that we stick to defining the meme as that which is passed on by imitation.

1. Introduction

There are many ways of defining the meme but there are two that we should perhaps take particularly seriously. First, Dawkins, who coined the term meme, described memes as units of cultural transmission which "*propagate themselves in the meme pool by ... a process which, in the broad sense, can be called imitation*" (Dawkins, 1976 p 192). Second, the Oxford English Dictionary defines a meme as follows: "*meme (mi:m), n. Biol. (shortened from mimeme ... that which is imitated, after GENE n.). An element of a culture that may be considered to be passed on by non-genetic means, esp. imitation*". Both these definitions include the critical point that memes are cultural information that is copied, and that it is copied by imitation. The OED is arguably the most important dictionary of the English language and is, as far as I know, the first to include the word 'meme'. It would be unfortunate if memeticists began to use definitions of the meme that were incompatible with the dictionary definition, unless there were good reasons for doing so.

Some technical definitions are quite unlike the dictionary one, but are nonetheless perfectly compatible with it. A good example is Wilkins's: "*A meme is the least unit of sociocultural information relative to a selection process that has favorable or unfavourable selection bias that exceeds its endogenous tendency to change.*" This is useful because it emphasizes, first, that the size of the relevant unit is not fixed but can vary in different contexts and, second, the importance of fidelity (i.e. the stability or resistance to change of the information). In this way Wilkins's (1998) definition of the meme is similar to Williams's (1966) definition of the gene. This definition may be useful for theoretical purposes but is too complicated for more general use, or for popular treatments of memetics. However this is not a problem since Wilkins's definition does not conflict with the OED definition.

Some other definitions clearly are incompatible with the OED. Some, for example, imply that almost everything we know or experience can count as a meme, whether acquired by imitation or not (e.g. Brodie, 1996; Gabora, 1997; Lynch, 1996). Brodie includes operant conditioning, and indeed all conditioning, as memetic. Gabora goes even further and includes ideas, perceptions, emotions, attitudes, and indeed "*anything that can be the subject of an instant of experience*". According to this broadest definition a garden frog would have a mass of memes (even though it is totally incapable of imitation or any kind of culture) because it has perceptions and emotions, and is capable of many kinds of learning.

I shall argue that these broader definitions are deeply confusing. They take away the idea of the meme as a replicator (which was the original reason for its invention, and provides its context within evolutionary theory), ignore the idea that memes must be passed on by some kind of copying, and merely add confusion to the already difficult problem of understanding consciousness. I suggest we are better to stick to the original definition of the meme as transmitted by imitation.

1.1 Defining Imitation

What is imitation? In this paper I want to tackle the question from two directions. First I will consider simpler kinds of learning and cognitive processes which may, or may not, be counted as imitation. Second I will consider whether imitation includes all higher-order human cognitive processes, such as speech, reading, teaching and instruction, upon which much of our cultural life depends. I will argue that when we have clarified these issues we will no longer have serious problems in defining the meme.

There is a long history of research on imitation in both animal behavior and human social psychology (for review see Whiten and Ham, 1992). In the nineteenth century Darwin collected many examples of what he took to be imitation in animals, as did Romanes (1882, 1883) but they did not define what they meant by imitation. Baldwin (1902) gave imitation a central role in his theories of evolution, pointing out that all adaptive processes can be seen as imitative - perhaps foreshadowing the universal Darwinism that today enables comparisons between biological evolution and memetic evolution (e.g. Dawkins, 1976; Plotkin, 1993). The psychologist, Thorndike (1898), was possibly the first to provide a clear definition of imitation as "*learning to do an act from seeing it done*".

Thorndike's definition (though confined to visual information) captures the essential idea that in imitation a new behavior is learned by copying it from someone else. One hundred years later we can see the importance of this point in distinguishing imitation from simple contagion and from other kinds of learning. These other kinds of learning can be divided roughly into individual learning and non-imitative social learning.

2. Contagion

The term "contagion" is often associated with memetics. We may say that certain memes are contagious, or more contagious than others. We may treat the spread of memes as comparable with the spread of infectious or contagious diseases and use models derived from epidemiology

(Lynch, 1996). The term social contagion is often used to include phenomena that are certainly memetic, such as the spread of fads, hysterical reactions (Showalter, 1997), or even suicide (Marsden, 1997). However, the term is used in confusing ways (Levy & Nail, 1993) and there is one kind of contagion that we must clearly distinguish from imitation.

This is what has variously been called instinctive imitation, imitative suggestion, social facilitation, coaction, and (simply) contagion (Whiten & Ham, 1992). Examples in humans include the spread of yawning, coughing or laughter. All these behaviors are extremely contagious. Indeed it can be difficult not to laugh if everyone around you is already laughing. This kind of contagion probably relies on specific stimulus feature detectors which detect laughing or yawning in someone else and then trigger the same innate behavior as the response. In other animals there are many examples of contagious vocalizations, such as alarm calls. Most vertebrates yawn and some animals, such as chimpanzees, laugh in response to tickling and play, but contagious laughter appears to be limited to humans (Provine, 1996).

This kind of contagion is not true imitation. We can see why by considering Thorndike's simple definition. Yawning, coughing and laughing are innate behaviours. When we start laughing because everyone else is laughing we have not learned how to do an act. We already knew how to laugh, and the kind of laugh we make is not modelled on the laugh we hear. So this kind of contagion is not imitation and should not be counted as memetic.

3. Individual Learning

In individual learning a person or animal learns something by itself, without anyone else necessarily being involved. There are traditionally two major types of learning in psychology - classical conditioning and operant conditioning.

3.1 Classical conditioning

Classical conditioning is when two stimuli become associated by repeated pairing. In the best known experiments Pavlov paired sounds with the smell of meat and found that dogs then salivated to the sounds even without any meat. Classical conditioning is widespread in the animal kingdom, for example when animals learn to distinguish palatable foods from poisonous foods, or learn other important facts about their environment. It occurs in humans whenever we associate two things together because they have previously been paired, whether those things are sights, sounds, tunes, ideas or pain. Behavior is changed by the process but nothing is passed on by imitation from one person to another, so the process is not memetic.

You may say that Pavlov, in setting up the experiments in the first place, was passing on something to his dogs. However, the dogs were not imitating him. There is no replication or copying of behavior from Pavlov to his dogs. Similarly if you have a dog or cat, it probably starts salivating at the sound of the fridge opening or the knife hitting the food dish. Or maybe it gets frightened at the sight of a new flea collar. This is classical conditioning at work. You have certainly trained the animals by the contingencies you set up, but there is no imitation involved.

3.2 Operant conditioning

Operant conditioning is when a behavior made by an animal is either rewarded or punished and therefore either increases or decreases in frequency. A hundred years ago Thorndike studied this kind of trial and error learning in cats trying to escape from specially designed boxes. In the 1930s Skinner famously provided animals with levers which, when pressed, caused food to be delivered. Rats, pigeons and other animals quickly learn to press the levers and their subsequent behavior depends on the schedules of reinforcement used.

Skinner (1953) pointed out the similarity between operant conditioning and natural selection - some behaviors are positively selected and others weeded out. In this way learning can be seen as an evolutionary system in which the behaviors are the replicators. Several selection theories of learning and of brain development have since been proposed (e.g. Calvin, 1987; Edelman, 1989; Plotkin, 1993), and are important for understanding the breadth of application of Darwinian processes. However, as long as the behaviors cannot be passed on to someone else by imitation then they do not count as memes and the selection is not memetic selection.

Much of human learning is Skinnerian and not memetic. Whether consciously or not, parents shape their children's behavior by the way they reinforce them. The most effective reward for children is attention and rewards work better than punishment. So if parents pay lots of attention to their children when they are behaving well, and act uninterested when they scream or have tantrums, then behaving well is in the best interests of the children and they will do it. The parents' behavior can be seen as part of the environment in which the children learn, or as part of a complex pattern of social learning (discussed below). Either way if the children are not imitating the parents then the process is not memetic.

We learn many things by trial and error, such as the physical skills of walking without falling over or riding a bike, or general ways of interacting with other people and the world. For example, people who are generally rewarded for hard work and persistence will behave differently from people whose efforts are met with arbitrary results. Of course memes may be involved - such as the very idea of riding a bike in the first place - but whenever we repeat actions that led to successful outcomes and suppress actions that led to pain or failure, then we are learning for ourselves by operant conditioning. We are not acquiring new memes.

3.3 Non-memetic learning

There are other kinds of learning that are also not memetic such as the formation of cognitive maps. Many animals develop complex mental maps of their environment without which they could not live at all, whether they are cats, rats, insects or birds. Some have complex territorial systems in which boundaries are carefully guarded, some (like squirrels for example) hide large numbers of food items and are able accurately to find them again, while others use well known paths to explore and find food. The information in the maps is learned by exploration and conditioning. There is no imitation involved. Similarly we develop complex cognitive maps of our own house and garden, the city we live in, and the places we go for our holidays. We can find our way around these places and conjure them up in our imagination. All this is individual learning and not memetic.

In practice we may not always be able to tease out those things we have individually learned by conditioning from those we have learned by imitation, and very often both are involved - but in principle the two are different. We know lots of things that are not memes.

4. Social Learning

Social learning means learning something from other people, (or, more generally, from conspecifics). Very often classical and operant conditioning are the basic processes involved, but something is learned in a way that involves other people or animals.

Social learning includes true imitation, but there are other kinds of social learning as well. According to Heyes (1993) the difference is best explained like this. Imitation means learning something about the form of behavior through observing others, while other kinds of social learning are learning about the environment through observing others. I like to think of the difference in terms of copying. In true imitation something about the action is copied from actor to imitator, while in other forms of social learning nothing is copied. This is important because evolutionary processes depend on there being something that is copied or replicated. Note that this fits well with Thorndike's definition of imitation as "*learning to do an act from seeing it done*". If memes depend on imitation for their transmission then we need to be clear about how to distinguish true imitation, which involves learning by copying a new form of behavior, from other kinds of social learning which do not.

4.1 Stimulus enhancement, local enhancement, and goal emulation

In 1921, in the south of England, some small garden birds called tits were seen prising open the wax-board tops of milk bottles left on the doorstep. The habit later became widespread across England and some parts of Scotland and Wales, with other species of bird joining in, and foil tops being pecked as well. It seemed that the tits learned from each other because this new behavior spread gradually from village to village, and across different areas, although it was obviously independently reinvented many times (Fisher & Hinde, 1949). The spread of milk-bottle pecking was a simple cultural phenomenon but purists would argue that it was based not on imitation, but on social learning (Sherry & Galef, 1984). Imagine that one bird learned, by trial and error, that there was cream under the bottle top. Then imagine another bird came by and saw the pecking and the obviously pecked top. Pecking is a natural action for tits and their attention can easily be drawn to something like a pecked top by the actions of other birds. So now the second bird is more likely to land on the bottle and peck too. Reinforcement from the cream now means that this bird is likely to repeat the action. It may then be seen by other birds. So this learning involves operant conditioning (the effect of the cream), is a kind of social learning (because another bird is involved), but is not true imitation (because the pecking is not actually copied). The fact that the birds used lots of different methods for opening the bottles also suggests they did not learn by direct imitation.

This kind of social learning is sometimes called "stimulus enhancement" - the stimulus, in this case the bottle top, has become more readily noticed by the birds. Another form of social learning that is not imitation is called "local enhancement". This is when attention is directed towards a specific place. For example, animals learn from each other which objects or places to

fear or ignore. Birds and rabbits learn not to fear trains by following others who are not afraid and therefore become used to the frightening noise. Rabbits can therefore establish warrens on railway embankments even though a naive rabbit from somewhere else would run in terror from the sound of a train. Yet another kind of social learning has been called "goal emulation", when one animal copies the goals or outcomes of another animal's behavior but without copying the form of that behavior itself. An example might be when an ape sees another ape getting food from a container and then uses a different method of its own invention for getting at that food. We can now see that none of these processes is true imitation because no new behaviors are copied from one animal to another (for reviews of social learning and imitation see Heyes and Galef, 1996; Whiten and Ham, 1992; Zentall and Galef, 1988). The behavior of one animal comes to be similar to that of another animal, but not by copying it.

Other famous examples that look like true cultural learning based on imitation include the troop of Japanese macaques that learned to wash sweet-potatoes, and chimpanzees that learned how to fish for termites by poking sticks into the mounds. However, both of these appear to depend on individual learning and the kinds of social learning described above, not on true imitation (Galef, 1992). So if you want to stick to the definition of memes as transmitted by imitation then you have to say that bottle-top pecking, termite-fishing and potato-washing are probably not memes.

5. True Imitation

The comparison with other forms of social learning raises the question whether true imitation occurs at all in non-human animals.

5.1 Vocal imitation in birds and dolphins

There is no doubt that there are examples of vocal imitation in birds and cetaceans. Song birds have been treated as a special case since research on imitation first began a hundred years ago (Bonner, 1980; Delius, 1989; Thorndike, 1898; Whiten and Ham, 1992). This is partly because imitation in birds is generally confined to sounds, and to rather specific kinds of sound at that (with the possible exception of parrots who may be able to imitate simple gestures). Many songbirds have long traditions. The young learn what to sing by imitating their parents or neighbors. In chaffinches, for example, the nestling may hear its father sing long before it is capable of singing itself. A few months later it begins to make a wide variety of sounds, gradually narrowing down to the song it heard as a chick. Experiments show that there is a critical period for learning and that the bird has to hear its own song and match it to the remembered song it is imitating. Hand-raised birds can learn songs from tape recorders and adopted birds sing songs more like their adopted, not biological, parents. Some species learn many songs from neighbors and a few, like parrots and mynahs, can imitate human speech.

Dolphins can also copy vocalizations, and young dolphins produce a wide variety of sounds which they later cut down. Captive bottlenose dolphins have been shown to easily imitate artificial signals relating to specific objects and use these new signals in spontaneous play (McCowan & Reiss, 1997). So we can count dolphin whistles and bird songs as memes, and indeed the cultural evolution of chaffinch song has been studied in terms of the mutation, flow

and drift of song memes (Lynch, Plunkett, Baker and Jenkins, 1989). These very specific kinds of imitation are therefore unlike the examples of social learning we were considering before.

5.2 Imitation in humans and other animals

As for other species, the picture is unclear. There have been claims of imitation (other than vocalization) in parrots, budgerigars, pigeons and rats, though all the claims have also been disputed (see Heyes & Galef, 1996). Dolphins can apparently mimic familiar behaviors but have not so far been shown to copy novel behaviors (Bauer & Johnson, 1994). Chimpanzees and gorillas that have been brought up in human families occasionally imitate in ways that their wild counterparts do not (Tomasello, Kruger & Ratner, 1993). However, when apes and human children are given the same problems, only the children readily use imitation to solve them (Call and Tomasello, 1995).

Humans, therefore, seem to differ considerably from all other species. They are "*the consummate imitative generalist*" (Meltzoff, 1988, p 59). Human infants are able to imitate a wide range of vocal sounds, body postures, actions on objects, and even completely arbitrary actions like bending down to touch your head on a plastic panel. By 14 months of age they can even delay imitation for a week or more (Meltzoff, 1988), and they seem to know when they are being imitated by adults (Meltzoff, 1996). Unlike any other animals we readily imitate almost everything and anything.

If we define memes as transmitted by imitation then we must conclude that only humans are capable of extensive memetic transmission. Some other theorists have included all forms of social learning in their definitions of cultural evolution (e.g. Boyd and Richerson, 1985; Delius, 1989; Plotkin, 1996) and their mathematical models may usefully apply to all. However, I suggest that it will be better for memetics to stick to the original definition of memes.

5.3 Only imitation sustains a true evolutionary process.

One might argue that both social learning and imitation allow information about behavior to be transmitted and that the difference is only one of fidelity, longevity or fecundity. Indeed Heyes (1994) does just this, arguing that the difference lies primarily in longevity. However, I suggest that the other forms of social learning do not support a replication system with true heredity.

Although new behaviors can be passed on by other kinds of social learning, the process is cumbersome. For example, one animal must invent a new behavior during individual learning and then somehow lead a second animal into such a situation that it is likely to learn the same new behavior - or perhaps the first can behave in such a way as to change the contingencies of learning for the second animal so that it learns the same (or a similar) new behavior. Most importantly, in these cases, the behavior must be created anew each time by the learner. The social situation and the behavior of the other animal plays a role, but the details of the first behavior are not transmitted and therefore cannot be built upon and refined by further selective copying. In this sense, then, there is no true heredity. This means there is no new replicator, no true evolution, and therefore the process should not be considered as memetic.

By contrast, the skill of generalized imitation means that humans can invent new behaviors of almost unlimited kinds and pass them on to each other by a kind of copying. If we define memes as transmitted by imitation then whatever is passed on by this copying process is a meme. Memes fulfill the role of replicator because they exhibit all three of the necessary conditions; that is, heredity (the form and details of the behavior are copied), variation (they are copied with errors, embellishments or other variations), and selection (only some behaviors are successfully copied). This is a true evolutionary process.

6. Human Cultural Learning

We learn about our culture in many ways, including reading and writing, watching television, being deliberately taught by parents and school teachers, and by listening to the conversations of others. In any consideration of memetics, from its origins in Dawkins's work, right through to the present, we count as memes all of the cultural behaviors passed on in these various ways, including everything from fashions and habits, to political ideologies and scientific theories. We would be daft to redefine the meme in such a way that any of these was excluded, but this naturally raises the question of whether all these forms of learning can really be counted as imitation.

There have been many attempts to classify the kinds of learning that underlie human cultural transmission. For example Tomasello et al (1993) describe three forms of cultural learning; imitative learning, instructed learning, and collaborative learning. They argue that all these involve some kind of inter-subjectivity or perspective taking, with increasingly complex kinds of social-cognitive concepts and processes involved. However, some prefer not to speculate at all about the intentionality or hidden cognitive processes involved in cultural learning (Zentall, 1996) while others take up the substantial questions of just what kinds of perspective-taking, intentionality, mind-reading, or other complex cognitive processes are involved in just which kinds of learning and teaching (see the extensive commentaries following Tomasello et al, 1993). There is clearly no consensus here yet, and it will not help us with defining the meme to launch into these tricky issues, even though in the future of memetics these issues may be very important.

Heyes (1994) takes an entirely different route and argues that human cultural learning is different from animals' because it involves instruction and not imitation. However, this distinction will not work, partly because animals do on occasion use instruction without imitation (as in the examples of manipulating contingencies described above) and partly because human instruction often entails imitation (as in learning to write or cook). Heyes further argues that the creation of language and artifacts decouples cultural accumulation from the process of imitation, but this means denying an important role to imitation in either language or the creation of books, art, buildings and ideologies.

We may take a simpler position - that all these kinds of learning and teaching require at least the ability to imitate. Language learning is a good example. Although there are many arguments about just how much of language depends on having an innate grammar module (Pinker, 1994), there is no doubt that human language learning involves the imitation of sounds. Chinese children do not spontaneously start using French words, and German children do not suddenly

burst into Hindi. The sounds of words are acquired by imitating others. Reading and writing are also learned, at least to some extent, by imitation, as when the shape of a letter is meticulously copied.

When we read a story and then tell it to someone else is this imitation? I would say that it is. The skills involved may be far more complex than the kinds of imitation I have described above, but they have a basis in imitation and are of the same general form. Something about the story is internalized in the listener and then reproduced when she or he tells the story again. The same can be said of passing on religious or scientific ideas - the reader or hearer of the ideas must internalize them in some way and then reproduce them for another reader or listener.

I have no doubt that in the future memetics will become involved in discovering just what the cognitive processes are that are involved in teaching, learning, instruction, and any other kinds of cultural transmission, but for the moment I suggest that we may consider all of them as in some way being forms of imitation, or based on the ability to imitate. I assume that this is what Dawkins meant by "... *a process which, in the broad sense, can be called imitation*". He meant to include reading, writing, conversation, and academic study as "*in the broad sense... imitation*" and I think we should have no hesitation in continuing to do so.

7. Conclusion

My argument has been that the definition of the meme depends on, and should depend on, the concept of imitation. Therefore, only those things that can be passed on by imitation should count as memes.

This means we can immediately exclude many things that a few authors have confusingly included as memes, such as perceptions, emotional states, cognitive maps, experiences in general, or "*anything that can be the subject of an instant of experience*". Furthermore we can build on the long history of research in animal behavior to distinguish imitation from contagion, and from individual and social learning, and so to eliminate from memetics the catching of yawns or all the many things we each learn for ourselves, by ourselves.

This, I suggest, leaves us with a simple definition of the meme that not only makes it easy to decide what is and is not a meme, but also shows why it is that humans alone have produced complex culture. Humans are fundamentally unique not because they are especially clever, not just because they have big brains or language, but because they are capable of extensive and generalized imitation. I think we will discover that it is imitation that gave rise to our cleverness, big brains and language - and it is imitation that makes culture possible, for only imitation gives rise to a new replicator that can propagate from brain to brain, or from brain to artifact and back to brain. For all these reasons I suggest that we stick with the dictionary, and define the meme as that which is passed on by imitation.

THE FORGET-MEME-NOT THEORY

By
Susan Blackmore

This piece was published in the Times Higher Education Supplement 26th February 1999, with responses to it published 5th March 1999 (p19)

Why do some ideas evolve through history while others are lost in the annals of time? Memes, of course. Susan Blackmore outlines a theory that has split the academic world.

We humans are odd creatures. Like other animals we are born and die, and enjoy food and sex, but unlike other species we wear clothes and cook our food, watch movies, go hang gliding, and read newspapers. Why? Is it just that we are more intelligent, or more conscious?

A completely new answer is provided by the theory of memes. Memes are ideas, skills, habits, stories or inventions, which are passed from person to person by imitation. Like genes they compete to get copied, but unlike genes their competition is for space in our memories, and for the chance to get into books, magazines and television programs. The survivors in this game are the ones we see all around us. Just as genes have created our bodies, so memes have created our minds and our cultures.

This explains, so the theory goes, our incurably religious nature, our unusual forms of cooperation and altruism, our use of language, and our ability to defy our genes with birth control and genetic engineering. We humans, alone on this planet, are meme machines. The term 'meme' (to rhyme with cream or dream) was coined in 1976 by Richard Dawkins, in *The Selfish Gene*. The purpose of his book was to explain the power and generality of Darwin's great insight. What Darwin had realized was that a simple mindless process can account for evolution---without a designer. If you have creatures that vary, and if only some of them can survive, and if the survivors pass on to their offspring whatever it was that helped them survive, then the next generation must be better adapted than the first---and so the process goes on. In more modern terms, if you have variation, heredity and selection, then you must get, as philosopher Dan Dennett puts it "Design out of Chaos without the aid of Mind". And this inevitable process works on anything that is copied---not just genes.

To push home his point, Dawkins wanted another example, and so he invented the meme. He included "tunes, ideas, catch-phrases, clothes fashions, ways of making pots or of building arches." He mentioned scientific ideas and religions, fashions in dress or diet, ceremonies, customs and technologies---all of which are spread by one person copying another. Memes are inherited every time they are passed on. They vary all the time, as when you tell the story slightly differently, or mix up two ideas to produce a new one. And they undergo enormous selection pressure. Just think how many ideas you have come across in this newspaper. Only a tiny fraction will survive in your memory, and even fewer will be passed on again to someone else. These successful memes are the survivors, and are the ones that shape our minds and cultures.

If we could understand what makes for a successful meme, then we would have a whole new way of understanding our minds. This is the promise that memetics holds out---but can it really work?

At the heart of memetics is the idea that memes compete with genes, causing effects that could not be predicted by biology alone. This is nowhere more obvious than in the arena of sex. Sex sells. People pay attention, get aroused, and pay money for sex. The genes made us that way, for their own propagation. But this gives sex memes a boost. They get all over the place, and some of them do not benefit our genes. Take birth control. Pills and condoms and coils thrive because they promise all the pleasure of sex without the responsibility of childbirth. They get an unfair advantage too, by a simple bit of logic.

Compare two women---one with one child and one with six. Which of them is likely to spread more of her memes? The woman with one child has more time to meet people and chat, more time for a career, more time to become a politician, television presenter, or writer. So her memes spread far and wide, including those for birth control and a small family. This simple inequality helps the memes along.

Other gene-challenging memes include celibacy, martyrdom and, most recently, genetic engineering. We all appreciate the threat of genetic modification getting out of control but memetics allows us to see just how and why that can happen. If the memes can spread they will, and given human need and greed they will.

One of the strengths of memetics is to explain not only why we like good ideas, but why false and even harmful ones have such power over us--- because they are good replicators. Take religions. Dawkins has made himself extremely unpopular in some circles by calling religions "viruses of the mind". They sneak into our minds, avoid our memetic defenses, and get themselves propagated all around the world, even though their claims are false. Millions of people believe in God, the afterlife, the transubstantiation, and the virgin birth, without a shred of evidence. Why? Because these memes use clever tricks to get themselves copied, just like viruses do. Believers, once infected, will fight for their beliefs, build great cathedrals to inspire others, bring up their children to fear God and go to church, and spend inordinate amounts of time singing, praying, and reading holy books---in other words, passing on the memes. And if they start to doubt, they will be told that the faithful go to heaven---an invisible place you cannot visit until you are dead. No wonder religions spread.

Alternative therapies do too. You visit the homeopath who gives you a long explanation and some water to take. Like everyone else you are susceptible to the placebo effect, and feel better from the attention. So you keep taking the water and are convinced by the homeopathy memes as well. Or you consult your stars, or a Tarot reader, or a psychic. The psychic homes in on your personal troubles using feedback and subtle body cues. If you are lucky she is gifted and empathic and can really help. So you go away, not just feeling better and poorer, but more convinced by her memes and likely to tell your friends.

Like these superstitions, science itself is a system of memes, and inevitably includes false memes and viruses, but the difference is this. Right at the heart of science lies the principle of testing all

new memes against the facts. If they fail they are thrown out. This is the ultimate arbiter against which memetics itself will be judged. Unlike God, if it helps us explain and predict human nature, then it will thrive. Otherwise---out it goes.

But we had better start finding out soon. For the memes are rapidly taking off. We might think we humans designed all those computers and phone links for our own pleasure, but from the meme's-eye-view we are just their copying machines, and they are using us to design a vast planet-wide system for their own propagation. The mechanism is frighteningly simple. Like genes, memes have no foresight and no plans, they just multiply when they can. Memes that get onto computers are successful and easily copied. Memes that jump from city to city and continent to continent, in multiple accurate copies, do even better, and take with them the idea of the Internet itself. We can't stop this evolutionary process and we are not, and never have been, in control. We may have been the first meme machines on this planet, but we won't be the last.

What is a Meme?

"meme /mi:m/ n. L20.(f. Gk mimema. that which is imitated, after GENE.) Biol. An element of a culture or system of behaviour that may be considered to be passed from one individual to another by non-genetic means, esp. imitation". (Shorter Oxford English Dictionary) Derivatives: memetic a., memetics n. the science of memes. memeplex n. abbreviated from 'co-adapted meme complex'; a group of memes passed on together, e.g. religions, political ideologies and belief systems. meme pool n. all the memes in a population at a particular time. memetic engineering n. manipulating memes, as in psychotherapy, advertising or education.

Before 'meme' entered the OED in 1997 there were many other definitions, from the unhelpfully encompassing "anything that can be the subject of an instant of experience" to the awkwardly narrow "constellations of activated and non-activated synapses within neural memory networks". But the basic principle of memes is that people copy each other, and copying lets loose a new evolutionary process. From this perspective the best definition must be "A meme is that which is passed on by imitation".

The Tricks Memes Play

Dear Friend, pass on this letter and you will have good luck for a year. Have you ever fallen for a chain letter? Perhaps you got one urging you to send money or postcards or stamps, or the more sinister---Pass this on to ten of your friends or you will fall ill, die, and suffer a fate worse than death...?

These memes succeed because they use crude tricks to get themselves copied, together with threats or promises. Their modern versions are winging their way around the Internet, using up valuable resources for their own selfish propagation. A long-running warning from "Pen pal Greetings" begins "received this morning from IBM". It tells you (at great length) to warn all your friends not to open the dangerous "Trojan Horse" virus. So you pass on the friendly warning, not realizing, unless you are very wily, that the warning itself is the virus---this is what gets into millions of e-mail boxes all over the world.

Fortunately most memes succeed because we want to copy them, from useful inventions like cars and central heating to beautiful paintings, stories and music. There are languages and customs, political ideologies and scientific theories. All these count as memes because they are copied from person to person. But what we must remember is that memes succeed because we copy them---some for good reasons---others not.

What the Experts Say about Memetics

"I think memes provide a neat way of explaining some of the paradoxes of cultural transmission and, if they help with explaining something that important, there had better be a science of them." Nicholas Humphrey, senior research fellow, London School of Economics

"The idea of memes is a meaningless metaphor". Stephen Jay Gould, professor of zoology, Harvard University

"A surprising number of people these days even talk about `memes' ... Absurd as it may seem to imagine the seamless web of culture being disaggregated and transmitted between minds by gene-like replication, even some sociologists and philosophers have become captivated by the metaphor." Steven Rose, biologist, Open University

"It is an empty and misleading metaphor to call religion, science, or any other human activity a `virus' or `parasite'". Memes are a "useless and essentially superstitious notion." Mary Midgley, philosopher, Newcastle.

"Memetics needs to come up with supported, unique predictions and/or an existence proof to become valuable. The challenge to our speakers is to provide some support---either theoretical or empirical---for the meme hypothesis." Robert Aunger, anthropologist, Cambridge.

Susan Blackmore is Senior Lecturer in Psychology at the University of the West of England, Bristol, and author of The Meme Machine, Oxford University Press. The first academic conference on memes will be held at King's College Cambridge, June 3 and 4. Speakers include Dan Sperber, Dan Dennett, John Maynard Smith and Susan Blackmore

THE POWER OF THE MEME MEME

By

Susan Blackmore

Department of Psychology
University of the West of England
Bristol BS16 2JP

For *Skeptic* June 1997, Vol 5, #2, pp43--49

Without the theory of evolution by natural selection nothing in the world of biology makes much sense. Without Darwin and neo-Darwinism, you cannot answer questions like “Why do bats have wings? Why do cats have five claws? or Why do our optic fibres cross in front of our retinas?” You can only fall back on appeals to an imaginary creator.

I am going to make a bold claim.

Without the theory of evolution by memetic selection nothing in the world of the mind makes much sense. Without memetics you cannot answer questions like “Why can’t I get that thought out of my mind? Why did I decide to write this article and not that one? Who am I?” Without memetics you can only fall back on appeals to an imaginary conscious agent.

In this article I want to lay the groundwork for a theory of memetics and see how far we can get. I shall outline the history and origins of the idea, explore how it has been used, abused, and ignored, and how it has provided new insight into the power of religions and cults. I shall then take on a meme’s eye view of the world and use this to answer five previously unanswered questions about human nature. Why can’t we stop thinking? Why do we talk so much? Why are we so nice to each other? Why are our brains so big? And, finally, what is a self?

I have tried to write the sections to stand alone. If you only want to read some of them I suggest you read the section Taking the meme’s eye view, and pick any others that take your fancy.

A History of the Meme Meme

In 1976 Dawkins published his best-selling *The Selfish Gene*. This book popularised the growing view in biology that natural selection proceeds not in the interest of the species or of the group, nor even of the individual, but in the interest of the genes. Although selection takes place largely at the individual level, the genes are the true replicators and it is their competition that drives the evolution of biological design.

Dawkins, clear and daring as always, suggested that all life everywhere in the universe must evolve by the differential survival of slightly inaccurate self-replicating entities; he called these “replicators”. Furthermore, these replicators automatically band together in to groups to create systems, or machines, that carry them around and work to favour their continued replication. These survival machines, or “vehicles” are our familiar bodies - and those of cats, e-coli and cabbages - created to carry around and protect the genes inside them.

Right at the end of the book he suggests that Darwinism is too big a theory to be confined to the narrow context of the gene. So he asks an obvious, if provocative, question. Are there any other replicators on our planet? Yes, he claims. Staring us in the face, though still drifting clumsily about in its primeval soup of culture, is another replicator - a unit of imitation. He gave it the name "meme" (to rhyme with "dream" or "seem") and as examples suggested "tunes, ideas, catch-phrases, clothes fashions, ways of making pots or of building arches." Memes are stored in human brains and passed on by imitation.

In just those few pages he laid the foundations for understanding the evolution of memes. He discussed their propagation by jumping from brain to brain, likened them to parasites infecting a host, treated them as physically realised living structures, and showed how mutually assisting memes will group together just as genes do. He argued that once a new replicator arises it will tend to take over and begin a new kind of evolution. Above all he treated memes as replicators in their own right, chastising those of his colleagues who tended always to go back to "biological advantage" to answer questions about human behaviour. Yes, he agreed, we got our brains for biological (genetic) reasons but now we have them a new replicator has been unleashed and it need not be subservient to the old. In other words, memetic evolution can now proceed without regard to its effects on the genes.

A few years later Douglas Hofstadter wrote about viral sentences and self-replicating structures in his *Scientific American* column *Metamagical Themas*. Readers replied, with examples of text using bait and hooks to ensure its own replication. They suggested viral sentences from the simplest instruction, such as "Copy me!", through those with added threats ("Say me or I'll put a curse on you") or promises ("I'll grant you three wishes"), to examples of virulent chain letters (Hofstadter, 1985, p 53). One reader suggested the term memetics for the discipline studying memes. Yet memetics did not really take off.

Why not? The basic idea is very simple. If Dawkins is right then everything you have learned by imitation from someone else is a meme. This includes all the words in your vocabulary, the stories you know, the skills and habits you have picked up from others and the games you like to play. It includes the songs you sing and the rules you obey. So, for example, whenever you drive on the right (and I on the left!), eat a hamburger or a pizza, whistle "Happy Birthday to You" or "Mama I love you" or even shake hands, you are dealing in memes. Memetics is all about why some memes spread and others do not.

The greatest proponent of memetics since Dawkins has been the philosopher Dan Dennett. In his books *Consciousness Explained* (1991) and *Darwin's Dangerous Idea* (1995) he expands on the idea of the meme as replicator.

In *The Origin of Species*, Darwin (1859) explained how natural selection must happen if certain conditions are met. If there is heredity from parent to offspring, variation among the offspring, and not all the offspring can survive - then selection must happen. Individuals who have some useful advantage "have the best chance of being preserved in the struggle for life" (Darwin, 1859, p 127, and see Dennett, 1995, p 48) and will then pass on this advantage to their offspring. Darwin clearly saw how obvious the process of natural selection is once you have grasped it. It just must happen.

Dennett describes evolution as a simple algorithm - that is, a mindless procedure that when carried out must produce a result. For evolution you need three things - heredity, variation and selection - then evolution is inevitable. You need not get us, of course, or anything remotely like us; for evolution has no plans and no foresight. Nevertheless, you must get something more complex than what you started with. The evolutionary algorithm is “a scheme for creating Design out of Chaos without the aid of Mind” (Dennett, 1995, p 50). This, says Dennett, is Darwin’s Dangerous Idea.

No wonder people have been terrified of it, and fought so hard against it. It is outrageously simple and terrifyingly powerful.

If evolution is an algorithm then it should be able to run on different substrates. We tend to think of evolution as depending on genes because that is the way biology works on this planet, but the algorithm is neutral about this and will run wherever there is heredity, variation and selection. Or -as Dawkins puts it - a replicator. It doesn’t matter which replicator. If memes are replicators then evolution will occur.

So are memes replicators?

There is enormous variety in the behaviours human beings emit, these behaviours are copied, more or less accurately by other human beings, and not all the copies survive. The meme therefore fits perfectly with the scheme of heredity, variation and selection. Think of tunes, for example. Millions of variants are sung by millions of people. Only a few get passed on and repeated and even fewer make it into the pop charts or the collections of classics. Scientific papers proliferate but only a few get long listings in the citation indexes. Only a few of the disgusting concoctions made in woks actually make it onto the TV shows that tell you how to Wok things and only a few of my brilliant ideas have ever been appreciated by anyone! In other words, competition to get copied is fierce.

Of course memes are not like genes in many ways and we must be very careful in applying terms from genetics to memes. The copying of memes is done by a kind of “reverse engineering” by one person copying another’s behaviour, rather than by chemical transcription. Also we do not know just how memes are stored in human brains and whether they will turn out to be digitally stored, like genes, or not. However, the important point is that if memes are true replicators, memetic evolution must occur.

Dennett is convinced they are and he explores how memes compete to get into as many minds as possible. This competition is the selective force of the memosphere and the successful memes create human minds as they go, restructuring our brains to make them ever better havens for more memes. Human consciousness, claims Dennett, is itself a huge meme-complex, and a person is best understood as a certain sort of ape infested with memes. If he is right then we cannot hope to understand the origins of the human mind without memetics.

This makes it all the more fascinating that most people interested in the human mind have ignored memetics or simply failed to understand it. Mary Midgley (1994) calls memes “mythical entities” that cannot have interests of their own; “an empty and misleading metaphor”. In a

recent radio debate, Stephen Jay Gould called the idea of memes a “meaningless metaphor” (though I am not sure one can actually have a meaningless metaphor!). He wishes “that the term “cultural evolution” would drop from use.” (Gould, 1996, p 219-20).

The word “Meme” does not even appear in the index of important books about human origins and language (e.g. Donald, 1991; Dunbar, 1996; Mithen, 1996; Pinker, 1994; Tudge, 1995; Wills, 1993), in an excellent collection on evolutionary psychology (Barkow, Cosmides and Tooby, 1992), nor in books about human morality (Ridley, 1996; Wright, 1994). Although there are many theories of the evolution of culture, almost all make culture entirely subservient to genetic fitness, as in Wilson’s (1978) metaphor of the genes holding culture on a leash or Lumsden and Wilson’s claim that “the link between genes and culture cannot be severed” (1981, p 344). Cavalli-Sforza and Feldman (1981) treat “cultural activity as an extension of Darwinian fitness” (p 362) and even Durham (1991), the only one to use the word “meme”, sticks to examples of cultural features with obvious relevance to genetic fitness, such as color naming, dietary habits and marriage customs. Perhaps Boyd and Richerson (1990) come closest to treating the cultural unit as a true replicator. However, they still view “genetic and cultural evolution as a tightly coupled coevolutionary process in humans” (Richerson & Boyd, 1992, p 80).

As far as I can understand them, no one except Cloak (1975) and Dawkins treats their unit of cultural exchange as a true replicator. If there is a continuum from Gould’s outright rejection at one end, to Dawkins and Cloak at the other, then most lie in between. They accept cultural evolution but not the idea of a second replicator. When they say “adaptive” or “maladaptive” they mean for the genes. When it comes to the crunch they always fall back on appeals to biological advantage, just as Dawkins complained that his colleagues did twenty years ago. Dawkins is clear on this issue when he says “there is no reason why success in a meme should have any connection whatever with genetic success”. I agree. I am going to propose a theory of memetics that lies at the far end of this continuum. I suggest that once genetic evolution had created creatures that were capable of imitating each other, a second replicator was born. Since then our brains and minds have been the product of two replicators, not one. Today many of the selection pressures on memes are still of genetic origin (such as whom we find sexy and what food tastes good) but as memetic evolution proceeds faster and faster, our minds are increasingly the product of memes, not genes. If memetics is true then the memes have created human minds and culture just as surely as the genes have created human bodies.

Religions as Co-Adapted Meme-Complexes

Dawkins (1976) introduced the term co-adapted meme-complex. By this he meant a group of memes that thrive in each others’ company. Just as genes group together for mutual protection, leading ultimately to the creation of organisms, so we might expect memes to group together. As Dawkins (1993) puts it “there will be a ganging up of ideas that flourish in one another’s presence”.

Meme-complexes include all those groups of memes that tend to be passed on together, such as political ideologies, religious beliefs, scientific theories and paradigms, artistic movements, and languages. The most successful of these are not just loose agglomerations of compatible ideas,

but well structured groups with different memes specialising as hooks, bait, threats, and immune system. (Memetic jargon is still evolving and these terms may change but see Grant's "memetic lexicon" (Grant, 1990)).

When I was about ten years old I received a post card and a letter that contained a list of six names and instructed me to send a post card to the first name on the list. I was to put my own name and address at the bottom and send the new list to six more people. It promised me I would receive lots of postcards.

This was a fairly innocuous chain letter as these things go, consisting just of a bait (the promised postcards) and a hook (send it to six more people). Threats are also common (send this on or the evil eye will get you) and many have far worse consequences than a waste of stamps. What they have in common is the instruction to "duplicate me" (the hook) along with co-memes for coercion. These simple little groups can spread quite well.

With the advent of computers viral meme-groups have much more space to play in and can leap from disk to disk among "unhygienic" computer users. Dawkins (1993) discusses how computer viruses and worms use tricks to get themselves spread. Some bury themselves in memory only to pop up as a time bomb; some infect only a small proportion of those they reach, and some are triggered probabilistically. Like biological viruses they must not kill their host too soon or they will die out. Their final effect may be quite funny, such as one that makes the Mackintosh's loudspeaker say "Don't Panic!", but some have clogged up entire networks and destroyed whole doctoral theses. My students have recently encountered a virus in WORD6 that lives in a formatting section called "Thesis" - tempting you to get infected just when your year's work is almost finished. No wonder we now have a proliferation of anti-virus software - the equivalent of medicine for the info-sphere.

Internet viruses are a relatively new arrival. Last week I received a very kind warning from someone I've never met. "Do not download any message entitled "Penpal Greetings"" it said - and went on to warn me that if I read this terrible message I would have let in a "Trojan Horse" virus that would destroy everything on my hard drive and then send itself on to every e-mail address in my mail box. To protect all my friends, and the world-wide computer network, I had to act fast and send the warning on to them.

Have you spotted it? The virus described does not make sense - and does not exist. The real virus is the warning. This is a very clever little meme-complex that uses both threats and appeals to altruism to get you - the silly, caring victim - to pass it on. It is not the first - "Good Times" and "Deeyenda Maddick" used a similar trick - and it probably won't be the last. However, as more people learn to ignore the warnings these viruses will start to fail and perhaps that will let in worse viruses, as people start to ignore warnings they ought to heed. So Watch Out! What does this have to do with religions? According to Dawkins, a great deal. The most controversial application of memetics is undoubtedly his treatment of religions as co-adapted meme-complexes (Dawkins 1976, 1993). He unashamedly describes religions as "viruses of the mind" and sets about analysing how they work.

They work because human brains are just what info-viruses need; brains can soak up information, replicate it reasonably accurately, and obey the instructions it embodies. Dawkins uses the example of Roman Catholicism; a gang of mutually compatible memes that is stable enough to deserve a name. The heart of Catholicism is its major beliefs; a powerful and forgiving God, Jesus his son who was born of a virgin and rose again from the dead, the holy spirit, and so on. If these aren't implausible enough you can add belief in miracles or the literal transubstantiation of wine into blood. Why should anyone believe these things? Dawkins explains.

Threats of hell-fire and damnation are an effective and nasty technique of persuasion. From an early age children are brought up by their Catholic parents to believe that if they break certain rules they will burn in hell forever after death. The children cannot easily test this since neither hell nor God can be seen, although He can see everything they do. So they must simply live in life-long fear until death, when they will find out for sure - or not! The idea of hell is thus a self-perpetuating meme.

And did I say "test" the idea? Some religious beliefs could be tested, such as whether wine really turns into blood, or whether prayer actually helps; hence the need for the anti-testing meme of faith. In Catholicism, doubt must be resisted, while faith is nurtured and respected. If your knowledge of biology leads you to doubt the virgin birth, - or if war, cruelty and starvation seem to challenge the goodness of God - then you must have faith. The story of Doubting Thomas is a cautionary tale against seeking evidence. As Dawkins puts it "Nothing is more lethal for certain kinds of meme than a tendency to look for evidence" (Dawkins, 1976, p 198) and religions, unlike science, make sure they discourage it. Also unlike science, religions often include memes that make their carriers violently intolerant of new and unfamiliar ideas so protecting themselves against being ousted in favour of a different religion - or none at all.

Finally the meme-complex needs mechanisms to ensure its own spread. "Kill the infidel" will dispose of the opposition. "Go forth and multiply" will produce more children to pass itself onto. So will forbidding masturbation, birth control or inter-faith marriages. If fear of going blind doesn't work, there are prizes in heaven for missionaries and those who convert unbelievers (Dawkins, 1993; Lynch, 1996).

Catholicism generally spreads from parent to child but celibate priests play a role too. This is particularly interesting since celibacy means a dead end for the genes, but not for the memes. A priest who has no wife and children to care for has more time to spread his memes, including that for celibacy. Celibacy is another partner in this vast complex of mutually assisting religious memes.

Dawkins (1993) gives other examples from Judaism, such as the pointlessness of Rabbis testing for the kosher-purity of food, or the horrors of Jim Jones leading his flock to mass suicide in the Guyana jungle. Today he might add "Heaven's Gate" to the catalogue. "Obviously a meme that causes individuals bearing it to kill themselves has a grave disadvantage, but not necessarily a fatal one. a suicidal meme can spread, as when a dramatic and well-publicised martyrdom inspires others to die for a deeply loved cause, and this in turn inspires others to die, and so on." (Dawkins, 1982, p 111).

He might equally have chosen Islam; a faith that includes the concept of the jihad or holy war, and has particularly nasty punishments for people who desert the faith. Even today the author, and heretic, Salman Rushdie lives in fear of his life because many Muslims consider it their holy duty to kill him. Once you have been infected with powerful memes like these you must pay a high price to get rid of them.

Lynch (1996) explores in depth some tricks used by religions and cults. “Honour thy father and mother” is an excellent commandment, increasing the chance that children will take on beliefs from their parents, including the commandment itself. As a secular meme it might not succeed very well, since kids would surely reject it if they thought it came straight from the parents. However, presented as an idea from God (who is powerful, all-seeing and punishes disobedience) it has a much better chance - a good example of memes “ganging up”.

Dietary laws may thrive because they protect against disease, but may also keep people in the faith by making it harder for them to adapt to other diets outside. Moral codes may enhance effective cooperation and survival but may also be ways of punishing lapses of faith. Observing “holy days” ensures lots of time for spreading the memes, and public prayers and grace at meals ensure that lots of people are exposed to them. Learning sacred texts by heart, and setting them to inspiring or memorable music ensures their longevity.

In the long history of religions most of them have spread vertically - that is from parent to child. Even today the best predictor of your religion is your parent’s religion - even if you think you rationally chose the “best” or “truest” one! However, today more and more new religions and cults spread horizontally - from any person to any other person. The two types use different meme tricks for their replication.

As an example of the first type Lynch (1996) gives the Hutterites. They average more than ten children per couple, a fantastic rate that is possibly helped by the way they distribute parental responsibility, making each extra child only a slightly greater burden for its natural parents. Other religions put more effort into conversion, like the evangelical faiths which thrive on instant rewards and spiritual joy on conversion.

In case I seem to be implying that people have deliberately manufactured religions this way, that is not at all what I mean. Look at it this way - imagine in the long, long history of human religious endeavour, all the millions and millions of different statements, ideas, and commandments that must have been uttered at some time or another. Which would you expect to have survived through to the present? The answer is, of course, the ones that just happened to have included clever tricks or come together with other ideas they could gang up with. The countless millions of other ideas have simply been lost. This is memetic evolution.

Taking the Meme’s Eye View

We are now ready to take on the meme’s eye view. The basic approach I take is this - imagine a world full of hosts for memes (e.g. brains) and far more memes than can possibly find homes. Now ask - which memes are more likely to find a safe home and get passed on again? It’s that simple.

In doing this I try to follow some simple rules.

First, remember that memes (like genes) do not have foresight!

Second, consider only the interests of the memes, not of the genes or the organism. Memes do not care about genes or people - all they do is reproduce themselves. Short-hand statements like “memes want x” or “memes try to do y” must always be translatable back into the longer version, such as “memes that have the effect of producing x are more likely to survive than those that do not.”

Third, memes, by definition, are passed on by imitation. So learning by trial and error or by feedback is not memetic, nor are all forms of communication. Only when an idea, behaviour or skill is passed on by imitation does it count as a meme. Now, remembering these rules, we can ask the question and see where it leads.

Imagine a world full of brains, and far more memes than can possibly find homes. Which memes are more likely to find a safe home and get passed on again?

Some of the consequences are startlingly obvious - once you see them. And some are frighteningly powerful.

I shall start with two simple ones, partly as exercises in thinking memetically.

1. Why can't we stop thinking ?

Can you stop thinking? If you have ever meditated you will know just how hard this is - the mind just seems to keep blithering on. If we were thinking useful thoughts, practising mental skills, or solving relevant problems there might be some point, but mostly we don't seem to be. So why can't we just sit down and not think? From a genetic point of view all this extra thinking seems extremely wasteful - and animals that waste energy don't survive. Memetics provides a simple answer.

Imagine a world full of brains, and far more memes than can possibly find homes. Which memes are more likely to find a safe home and get passed on again?

Imagine a meme that encourages its host to keep on mentally rehearsing it, or a tune that is so easy to hum that it goes round and round in your head, or a thought that just compels you to keep thinking it.

Imagine in contrast a meme that buries itself quietly in your memory and is never rehearsed, or a tune that is too unmemorable to go round in your head, or a thought that is too boring to think again.

Which will do better? Other things being equal, the first lot will. Rehearsal aids memory, and you are likely to express (or even sing) the ideas and tunes that fill your waking hours. What is the consequence? The memosphere fills up with catchy tunes, and thinkable thoughts. We all come across them and so we all think an awful lot.

The principle here is familiar from biology. In a forest, any tree that grows tall gets more light. So genes for growing tall become more common in the gene pool and the forest ends up being as high as the trees can make it.

We can apply the same principle again.

2. Why do we talk so much?

Imagine a world full of brains, and far more memes than can possibly find homes. Which memes are more likely to find a safe home and get passed on again?

Imagine any meme that encourages talking. It might be an idea like “talking makes people like you” or “It’s friendly to chat”. It might be an urgent thought that you feel compelled to share, a funny joke, good news that everybody wants to hear, or any meme that thrives inside a talkative person.

Imagine in contrast any meme that discourages talking, such as the thought “talking is a waste of time”. It might be something you dare not voice aloud, something very difficult to say, or any meme that thrives inside a shy and retiring person.

Which will do better? Put this way the answer is obvious. The first lot will be heard by more people and, other things being equal, simply must stand a better chance of being propagated. What is the consequence of this? The memosphere will fill up with memes that encourage talking and we will all talk an awful lot. And we do!

A simpler way of putting it is this:- people who talk more will, on average, spread more memes. So any memes which thrive in chatterboxes are likely to spread.

This makes me see conversation in a new light. Is all that talking really founded on biological advantage? Talking takes a lot of energy and we do talk about some daft and pointless things! Do these trivial and stupid thoughts and conversations have some hidden biological advantage? I would at least like to offer the suggestion that they do not. That we do all this talking and all this thinking merely because the memes that make us do it are good survivors. The memes seem to be working against the genes.

This sets the stage for a more audacious suggestion.

3. Why are we so nice to each other?

Of course we aren’t always nice to each other, but human co-operation and altruism are something of a mystery - despite the tremendous advances made in understanding kin selection and inclusive fitness, reciprocal altruism and evolutionarily stable strategies (see e.g. Wright, 1994; Ridley, 1996). Human societies exhibit much more cooperation than is typical of vertebrate societies, and we cooperate with non-relatives on a massive scale (Richerson and Boyd, 1992). As Cronin puts it, human morality “presents an obvious challenge to Darwinian theory” (Cronin, 1991, p325).

Everyone can probably think up their own favourite example. Richard Dawkins (1989 p 230) calls blood donating “a genuine case of pure, disinterested altruism”. I am more impressed by charitable giving to people in faraway countries who probably share as few of our genes as anyone on earth and whom we are unlikely ever to meet. And why do we hand in wallets found in the street, rescue injured wildlife, support eco-friendly companies or recycle our bottles? Why do so many people want to be poorly paid nurses and counsellors, social workers and psychotherapists, when they could live in bigger houses, attract richer mates, and afford more children if they were bankers, stock brokers or lawyers?

Many people believe all this must ultimately be explained in terms of biological advantage. Perhaps it will, but I offer an alternative for consideration; a memetic theory of altruism. We can use our, by now, familiar tactic.

Imagine a world full of brains, and far more memes than can possibly find homes. Which memes are more likely to find a safe home and get passed on again?

Imagine the sort of meme that encourages its host to be friendly and kind. It might be a meme for throwing good parties, for being generous with the home-made marmalade, or just being prepared to spend time listening to a friend’s woes. Now compare this with memes for being unfriendly and mean - never cooking people dinners or buying drinks, and refusing to give your time to others. Which will spread more quickly?

The first type, of course. People like to be with nice people. So those who harbour lots of friendliness memes will spend more time with others and have more chances to spread their memes. In consequence many of us will end up harbouring lots of memes for being nice to others.

A simpler way of putting it is this:- people who are altruistic will, on average, spread more memes. So any memes which thrive in altruistic people are likely to spread - including the memes for being altruistic.

You may wish to challenge any of the above steps. It is therefore reassuring to learn from many experiments in social psychology, that people are more likely to adopt ideas from people they like (Eagly and Chaiken, 1984). Whether this is a cause or a consequence of the above argument is debatable. It would be most interesting if psychological facts like this, or others such as cognitive dissonance, or the need for self esteem, could be derived from simple memetic principles - but that is a topic for another time!

For now we should consider whether the idea is testable. It predicts that people should act in ways that benefit the spread of their memes even at some cost to themselves. We are familiar with buying useful information, and with advertisers buying their way into people’s minds for the purposes of selling products, but this theory predicts that people will pay (or work) simply to spread the memes they hold - because the memes force them to. Missionaries and Jehovah’s Witnesses seem to.

Many aspects of persuasion and conversion to causes may turn out to involve meme-driven altruism. Altruism is yet another of the meme tricks that religions (those most powerful of meme-complexes) have purloined. Almost all of them thrive on making their members work for them and believe they are doing good.

Of course, being generous is expensive. There will always be pressure against it, and if memes can find alternative strategies for spreading they will. For example, powerful people may be able to spread memes without being altruistic at all! However, that does not change the basic argument - that altruism spreads memes.

You may have noticed that the underlying theme in all these arguments is that the memes may act in opposition to the interest of the genes. Thinking all the time may not use much energy but it must cost something. Talking is certainly expensive, as anyone who has been utterly exhausted or seriously ill will attest. And of course any altruistic act is, by definition, costly to the actor. I would say that this is just what we should expect if memes are true replicators. They do not care about the genes or the creatures the genes created. Their only interest is self-propagation. So if they can propagate by stealing resources from the genes, they will do so. In the next example we see the memes forcing the hand of the genes in a much more dramatic way.

4. Why are our brains so big?

Yes, I know this is an old chestnut, and there are lots and lots of good answers to the question. But are they good enough? Let us not forget how mysterious this issue really is. Brains are notoriously expensive both to build and to run. They take up about 2% of the body's weight but use about 20% of its energy. Our brains are three times the size of the brains of apes of equivalent body size. Compared to other mammals our encephalisation quotient is even higher, up to about 25 (Jerison, 1973; Leakey, 1994; Wills, 1993). On many measures of brain capacity humans stand out alone. The fact that such intelligence has arisen in an animal that stands upright may or may not be a coincidence but it certainly adds to the problem. Our pelvises are not ideally suited for giving birth to huge brains and so childbirth is a risky process for human beings - yet we do it. Why?

The mystery was deepened for me by thinking about the size of the biological advantage required for survival. In a study concerned with the fate of the Neanderthals, Zubrow (Leakey, 1994) used computer simulations to determine the effect of a slight competitive edge. He concluded that a 2% advantage could eliminate a competing population in less than a millennium. If we needed only such a tiny advantage why do we have such a huge one? Several answers have recently been proposed. For example, Dunbar (1996) argues that we need large brains in order to gossip, and we need to gossip as a kind of verbal grooming to keep very large bands of people together. Christopher Wills (1993) argues that the runaway evolution of the human brain results from an increasingly swift gene-environment feedback loop. Miller (1993) proposes that our vast brains have been created by sexual selection; and Richerson and Boyd (1992) claim they are used for individual and social learning, favoured under increasing rates of environmental variation.

What these authors all have in common is that their ultimate appeal is to the genes. Like Dawkins' bewailed colleagues, they always wish to go back to biological advantage. I propose an alternative based on memetic advantage.

Imagine early hominids who, for good biological reasons, gained the ability to imitate each other and to develop simple language. Once this step occurred memes could begin to spread, and the second replicator was born. Remember - once this happened the genes would no longer be able to stop the spread! Presumably the earliest memes would be useful ones, such as ways of making pots or knives, or ways of catching or dismembering prey. Let us assume that some people would have slightly larger brains and that larger brains are better copiers. As more and more people began to pick up these early memes, the environment would change so that it became more and more necessary to have the new skills in order to survive.

A person who could quickly learn to make a good pot or tell a popular story would more easily find a mate, and so sexual selection would add to the pressure for big brains. In the new environment larger brained people would have an advantage and the importance of the advantage would increase as the memes spread. It seems to me that this fundamental change in selection pressures, spreading at the rate of meme propagation, provides for the first time a plausible reason why our brains are totally out of line with all other brains on the planet. They have been meme-driven. One replicator has forced the moves of another.

5. Who am I?

We can now see the human mind as the creation of two replicators, one using for its replication the machinery created by the other. As Dennett pointed out, people are animals infested with memes. Our personalities, abilities and unique qualities derive from the complex interplay of these replicators. What then of our innermost selves - the "real me", the person who experiences "my" life?

I would say that selves are co-adapted meme complexes - though only one of many supported by any given brain (Blackmore, 1996). Like religions, political belief systems and cults, they are sets of memes that thrive in each other's company. Like religions, political belief systems and cults, they are safe havens for all sorts of travelling memes and they are protected from destruction by various meme-tricks. They do not have to be true.

In fact we know that selves are a myth. Look inside the brain and you find only neurons. You do not find the little person pulling the strings or the homunculus watching the show on an inner screen (Dennett, 1991). You do not find the place where "my" conscious decisions are made. You do not find the thing that lovingly holds all those beliefs and opinions. Most of us still persist in thinking about ourselves that way. But the truth is - there is no one in there!

We now have a radically new answer to the question "Who am I?", and a rather terrifying one. "I" am one of the many co-adapted meme-complexes living within this brain. This scary idea may explain why memetics is not more popular. Memetics deals a terrible blow to the supremacy of self.

The Future for Memes

The memes are out! For most of human history memes have evolved alongside genes. They were passed on largely vertically - from parent to child - and therefore evolved at much the same rate as genes. This is no longer true. Memes can leap from brain to brain in seconds - even when the brains are half a planet apart.

While some memes hang around in brains for weeks, months or years before being passed on, many now spread in multiple copies at the speed of light. The invention of the telephone, fax machine and e-mail all increase the speed of propagation of memes. As high speed, accurate, horizontal copying of memes increases we can expect some dramatic developments in the memosphere.

First, the faster memes spread the weaker is the hold of natural (genetic) selection. This relative uncoupling of genes and memes may mean that more than ever before memes will spread that are detrimental to their carriers. We may be seeing this already with some of the dangerous cults, fads, political systems, copy-cat crimes and false beliefs that can now spread so quickly. Second, we may expect memes to build themselves ever better vehicles for their own propagation. Genes have built themselves organisms to carry them around in. What is the memic equivalent? Artifacts such as books, paintings, tools and aeroplanes might count (Dennett, 1995) but they are feeble compared with computers or the Internet. Even these recent inventions are still largely dependent on humans for their functioning, and on the genes those humans are carrying - after all, sex is the most popular topic on the internet. So can the second replicator ever really break free? It might if ever we construct robots that directly imitate each other. Fortunately this is such a difficult task that it will not be achieved very soon and perhaps by then we will have a better understanding of memetics and be in a better position to cope with our new neighbours.

Conclusion

I have shown how a theory of memetics provides new answers to some important questions about human nature. If I am right, then we humans are the product of two replicators, not just one. In the past hundred years we have successfully thrown off the illusion that a God is needed to understand the design of our bodies. Perhaps in the next millennium we can throw off the illusion that conscious agents are needed to understand the design of our minds.

THE EVOLUTIONARY ECOLOGY OF SCIENCE

By

Marion Blute

Department of Sociology

University of Toronto at Mississauga

marion.blute@utoronto.ca

Abstract

In the study of sociocultural/memetic evolution, approaches modelled on population genetics (e.g. Cavalli-Sforza and Feldman 1981) and on systematics/taxonomy (e.g. Hull 1988) have been prominent but the influence of evolutionary ecology has been slight. In the tradition of Toulmin (1972) and Hull (1988) this paper is about cultural evolution in science. In particular, it applies some principles of evolutionary ecology to the scientific process. The effects of density, scale, frequency and heterogeneity on various strategies of research and teaching in science are considered. In the future, the analysis should be extended to the sociobiology of science including the relationship between supervisors and their graduate and postdoctoral students and among peers e.g. publishing and other forms of social collaboration.

Keywords: sociocultural evolution, cultural evolution, memetics, sociology of science, philosophy of science, science studies, evolutionary ecology

1 Introduction: Sociocultural/Memetic Evolution, Science and Evolutionary Ecology

Since Carl Degler's prize winning book (1991) documented the decline and subsequent revival of Darwinism in social thought, Darwinian-style evolution-based theorizing and research has continued to grow rapidly in a whole host of humanistic and social scientific disciplines and fields. It comes in three broad forms. These are: human behavioural ecology/evolutionary psychology/sociobiology emphasizing biological (gene-based) evolution, sociocultural evolutionism emphasizing sociocultural (social learning or meme-based) evolution, and gene-culture coevolution emphasizing their interaction (gene-culture coevolution). While not denying the utility of the others, this article is concerned exclusively with the second -- with sociocultural evolution. Among these, some find it useful or even necessary (after Dawkins 1976) to use the concept of memes, analogous to genes, for the basic units of hereditary information or replication involved, others are indifferent, and still others find it misleading. While those who find the meme concept misleading may be underestimating the similar ambiguity, even multiplicity, of gene concepts in biology, those who find it indispensable may be underestimating how much useful theorizing and research has gone on historically in biology including much taxonomy and ecology largely ignoring genes while working purely at the phenotypic level. Because, as Whiten put it: "that there are just two major forms of behavioural evolution, occurring through genetic and cultural transmission respectively must rank among the most exciting and fundamental discoveries of biology achieved over the last century and a half" (2001:359), I find myself in agreement with those who think it is more important to just get on with it. [note 1]

Social scientists and even humanists in a variety of fields have been getting on with it. These include not only epistemology (Campbell 1988: Part V, Plotkin 1994, Buskes 1998), anthropology (Sperber 1996, Cullen 2000, Ehrlich 2000) and sociology (Runciman 1989, Lenski et. al. 1994, Fog 1999) generally, but also more specific fields such as institutional economics (Boulding 1981, Nelson and Winter 1982), linguistics (Ruhlen 1994, Croft 2000), organizations (Aldrich 1999) and technology studies (Basalla 1988, Ziman 2000) in addition to memetics of course (Brodie 1996, Lynch 1996, Blackmore 1999 and Aunger 2000) to mention only some books.

On the topic of sociocultural evolution in science in particular which is the subject of this paper, Darwinian-style evolutionary approaches emerged more from the philosophy than from the sociology of science. Although Popper's (1963) falsificationism was evolutionary at least in the negative sense of selection against, in retrospect, it seems almost inevitable that once Kuhn (1962) started his revolution making philosophers of science more historically and sociologically aware, that a full-blown Darwinian-style evolutionary approach to science would emerge. The pioneer was Stephen Toulmin (1972) but eventually, more than anyone else, it was developed by David Hull. Hull's sophisticated *Science as a Process* (1988) is at once a treatise on the philosophy of science, the sociology of science, and evolutionary theory (whether instantiated biologically or socioculturally). Not immodestly, but accurately in my opinion, Hull views himself as the heir of Kuhn and Toulmin. The major elements of his evolutionary theory of science are "curiosity" (mutation), "credit" (descent) and "checking" (selection). While this paper is in the tradition of Hull's theory, there are some differences in emphasis. It places an equal emphasis on the acquisition of knowledge in science and its dissemination, it deals almost exclusively with dissemination through graduate and postdoctoral students rather than through peers by means of paper publishing etc. (the sociobiology of science is beyond the scope of this paper), and emphasizes more selection over descent (the reason for which follows).

In any evolutionary process, the currently existing array of forms is explained by constraints (most obviously the laws of physics and chemistry but there may be others), chance (mutation and sampling error in finite populations), history and selection. The three most important research programmes in evolutionary biology are population genetics (which deals with some of these formally), taxonomy which emphasizes history by building trees, and evolutionary ecology which emphasizes the forces of, and responses to, selection. In previous work on sociocultural evolution, approaches modelled on population genetics (particularly Cavalli-Sforza and Feldman 1981) and on taxonomy (particularly Hull, not surprisingly given that the science he studied was taxonomy) have been prominent but the influence of evolutionary ecology has been slight. While this paper is about cultural evolution in science then, it is particularly about evolution in science under different ecological conditions.

Darwin's theory of evolution was a theory 'that' natural selection, rather than 'of' natural selection. The *Origin of Species* contains no general theory of the circumstances under which selection favours this or that property of organisms. Evolutionary ecology is the discipline that attempts to fill this gap (Cockburn 1991, Bulmer 1994, Fox, Roff and Fairbairn 2001) see also the relevant parts of general ecology texts including (Begon, Harper and Townsend 1996, Pianka 1999, and Ricklefs and Miller 2000). Evolutionary ecology seeks a theoretical halfway house between the near-universal tautology of the fitness-selection nexus and the near-complete

historical specificity of the myriad details of what is adaptive in locally prevailing circumstances. Its research programme is in turn divided into a number of subbranches, each of which combines evolution and ecology with some other traditional field of biological study: physiology (Sibly and Calow 1986), development i.e. life histories (Roff 1992, Stearns 1992, Charnov 1993), behaviour (Krebs and Davies 1993, Krebs and Davies 1997) including foraging (Stephens and Krebs 1986), and extends even beyond populations to metapopulations (Rhodes, Chesser and Smith 1996, Hanski and Gilpin 1997, Hanski 1999). The appropriate terminology becomes long as in evolutionary physiological (or developmental or behavioural or metapopulational) ecology. In addition, an intersecting set of divisions pertain to the group studied microbial (Andrews 1991), plant (Bazzaz 1996), animal, and human (Smith and Winterhalder 1992). Despite this complexity, it is often recognized that similar principles should apply to all divisions (Andrews 1991) and at all scales (Bazzaz 1996).

The most important ecological conditions which control evolution are density (low versus high discussed in sections two and three) and scale (small versus large discussed in section five). These reflect the optimization approach (in the narrow sense) to evolutionary ecology. In both cases, alternatively or in addition, negative frequency dependence may obtain (it being advantageous to do the opposite of what others are doing). This is the game theory approach discussed with respect to density dependence in section four and with respect to scale dependence included in section five. In both cases as well, heterogeneity of conditions may obtain as discussed in section six. In all cases, the evolutionary-ecological theoretical approach is to ask, and try to answer logically, "Under alternative ecological conditions, what adaptations, or 'strategies' as they are called, would selection favour?" Given that the influence of evolutionary ecology on the study of sociocultural evolution and memetics has been slight as noted, the concepts employed may be largely unfamiliar to readers of this paper. If so, it might be helpful to follow the summaries in Table 1a (on density dependence and its complications) and in Table 1b (on scale dependence and its complications) as you go. For more interested or knowledgeable readers, a discussion of how the evolutionary ecology employed here differs from others where it does is included in the appendix.

2 Density Dependence: Primary Versus Secondary Research/Teaching

Much of modern evolutionary ecology can be understood as flowing from the premise that the most fundamental physical properties of the ecological environment energy content, time and space (whether literal or metaphorical, i.e. niche time/space) are what organisms are most liable to evolve adaptations to. Albeit controversial in some respects, the most general theory proposed to date and hence the most convenient to use to organize this discussion is the verbal theory of density-independent (r) versus density-dependent (K) selection (MacArthur 1962, MacArthur and Wilson 1967). [note 3] Consider the following specific interpretation of the former for individual growth in a homogeneous environment. When population density (measured for now in size) relative to resources [note 4] is low, selection favours spending on growth. This entails maximizing r (the intrinsic growth rate of the population measured in size) by acquiring as much in the way of resources as possible and engaging in intermediary (degradative) metabolism. When density is high on the other hand, selection favours investing in maintenance. This entails maintaining the population at or near the carrying capacity of the environment, K , by means of

intermediary (biosynthetic) metabolism, building up structures with some of the substances derived and excreting others. [note 5]

Table 1. Some Principles of the Evolutionary Ecology of Science [note 2]

Table 1a) Density-Dependent Selection

Homogeneous Environment Growth OR 3M's	
At Low Density or History of Catastrophes growth	At High Density or History of Bonanzas maintenance, motility, mutability
Heterogeneous Environment Flexibility	
Fine-grained Heterogeneity (environment changes/varies between low and high densities with high frequency relative to period/distance) morphological, physiological, behavioural change/differentiation	Coarse-grained Heterogeneity (environment changes/varies between low and high densities with long period/distance relative to frequency) phenotypic plasticity

Table 1b) Scale-Dependent Selection

Homogeneous Environment r/d OR t/s Growth	
In or History of Small-scale Environment rate/density growth	In or History of Large-scale Environment time/space growth
Heterogeneous Environment Flexibility	
Fine-grained Heterogeneity (environment changes/varies between small & large scales with high frequency relative to period/distance) morphological, physiological, behavioural change/differentiation	Coarse-grained Heterogeneity (environment changes/varies between small & large scales with long period/distance relative to frequency) phenotypic plasticity

There are many kinds of scientific research. New empirical research can yield knowledge, new theories, understanding, new combinations of these, explanations and predictions. New methods can alter the ways in which any of these kinds of research are conducted. Whatever classification of kinds of research one prefers, the analysis here is intended to apply to all of them but for convenience, the word "knowledge" will be used to apply to all. It has been a fundamental principle of the sociology of science since Merton (1973) virtually invented the subject, that scientists compete for status rather than wealth, income or power. They compete to have their work incorporated into that of others (through their direct cultural heirs -- graduate and postdoctoral students as well as indirectly through peers via publications with their influence or ancestry acknowledged in citations). In Hull's terminology, they compete for "credit". Of course just as organisms must grow and develop in order to reproduce, scientists must acquire knowledge i.e. do research in order to have something to communicate and receive credit for having done so. Imagine then members of a population of scientists competing to acquire knowledge from nature by means of research on a new topic or in a new field -- a low density or uncrowded environment. Because the topic or field is new, none of the competitors know very much and a whole world lies waiting to be discovered. Given the objective of maximizing personal knowledge, when under such benign conditions it pays to engage in as much primary research as possible, data is collected empirically, and axioms or postulates (or in multi-paradigm sciences theories themselves) are added. Complex inputs must additionally be analysed (broken down). In empirical research outliers must be identified, statistically significant results distinguished from the insignificant, repeatable results distinguished from the non-repeatable, and so on. Similarly in theoretical research analysis is necessary. Not only are axioms or postulates required, but theorems must be proven. As the topic or field matures however, competitors already possess a lot of knowledge and there is not much new left to be discovered.

That is not the end of the task however as has sometimes been thought (Horgan 1996). Knowledge must be maintained by what has sometimes been called "secondary research". The task of synthesis is primarily one of assimilating the new into the context of old ("adding new bricks to the wall" as the expression has it) but the positively misleading must be weeded out as well. At least three studies have shown that even articles which have been retracted continue to be cited (Campanario 2000), an extreme example of the necessity of such work. Other kinds of "repairs" are required -- for example errors corrected and findings rearranged in relation to one another. Much of the work of secondary research is performed by referees and writers of review articles, meta-analyses, textbooks, and other "secondary" literature with the goal of building durable knowledge. In science, as in life, low densities favour spending on growth particularly by acquisition and analysis; high densities favour investing in maintenance particularly by synthesis and rejection.

What applies individually in evolutionary ecology applies similarly demographically. When population density (measured now in numbers) is low relative to resources [note 6], selection favours spending on maximizing r (the growth rate of the population measured in numbers) by producing as many offspring as possible and "breaking down" by assessing quality. When density is high, selection favours investing in maintaining the population at or near the carrying capacity of the environment, K , by means of intermediary (biosynthetic) metabolism -- "building up" fewer offspring with parental care and "excreting" by practising active discrimination in favour of those assessed to be of high rather than low quality. In short, low densities favour

growth by quantity and assessment; high densities favour maintenance by quality and active discrimination. Again imagine members of a population of scientists competing in a low density environment, measured now in numbers. Competitors working on the new topic or field are few and a whole world lies waiting to be populated with researchers. Given the objective of maximizing public knowledge (Ziman 1968), under such benign conditions it pays to spend on what might be called "primary" teaching -- training as many graduate and post-doctoral students as possible and assessing quality. As the topic or field matures however, competitors are numerous and there is little room for more. Under such harsh conditions, it pays to invest in what might be called "secondary" teaching. Demographic success is better served by mentoring fewer students and pruning the "brood" to improve quality.

In summary, when densities are low, selection favours spending on maximizing r by acquiring knowledge and analysing it (primary research) and by teaching and assessing large numbers of graduate and postdoctoral students (primary teaching). When densities are high, it favours investing in maintaining K by synthesizing knowledge and weeding out inaccuracies (secondary research) and mentoring fewer students along with active discrimination (secondary teaching). Note that neither kind of strategy is intrinsically better than the other, rather, both should be similarly successful in their appropriate circumstances. A population that begins small and grows in size or numbers to become large and one which, already large, manages to remain so rather than declining are, at equal costs, equally successful. While often not so considered, scientists who add and those who maintain personal or public knowledge are contributing equally.

3 Density Dependence: Primary Research/Teaching Versus Moving or Innovating

A second alternative to maintenance at high densities is motility. Where (rather than when) population density measured in size is low, selection favours spending on growth, but where it is high, selection favours investing in motility -- dispersing in space to where circumstances are more favourable. This distinction is commonly drawn in evolutionary ecology for example "handle versus search", "exploit versus explore", or "assimilate versus migrate" in foraging theory and "competitive ability" versus dispersal in the study of life histories. Even in the absence of motility as conventionally understood, this distinction can be applicable. In branching growth forms, laterals are often devoted to consuming (e.g. leaves in plants eat sunlight) while leaders are often devoted to extending the plant's reach. Stems in plants photosynthesise very little but extend the plant's reach, functioning as a form of motility in sessile organisms (Andrews 1991). All that applies to individual growth applies equally to demographic growth. Where densities are low, selection favours a large "clutch size" -- offspring quantity. Where it is high, selection favours motile offspring which, following the logic of trade-offs, would be expected to be fewer initially.

In their research and teaching, scientists often have opportunities to cope with diminishing returns to primary research in a topic or field by escaping to a different, more promising one: from molecular genetics to molecular neurobiology, from the war on cancer to the war on aids, from youth in the 60's to the ageing population of the 90's, etc. Individual scientists prepared to translocate knowledge acquired in one context to another can be successful. Hull's own work applying concepts and theories acquired in evolutionary biology to the sociology of science is a

case in point. Not only do scientists engage in such strategies, they sometimes prepare their students to do so. For example, many mathematicians, physicists and computer scientists moved into finance a decade or so ago (Chance and Peterson 1999) and some of the former kinds of graduate programmes specifically trained at least some of their students to do so.

In addition to maintenance and motility, high densities should also favour mutability. In 1982, Walter Fitch a pioneer of the study of molecular evolution clearly described and predicted the existence of the phenomena that have come to be known as "adaptive" and "directed" mutation respectively. "The organism might be better off if it could vary its mutation rate upward in stressful times and downward in favourable times ... If the organism needs to change only a few of its genes, one would prefer to increase the mutation rate in those genes specifically ... I predict that a mechanism for just this will be found" (quoted in Hall 1998). In 1988 in *Nature* and in 1991 in *Genetics* Cairns et. al. and Cairns and Foster created something of a sensation by reporting just such results for an experimental system in *E. coli*. Eventually the dust settled and many of the mechanisms even of adaptive although not necessarily directed mutation in bacteria and yeast are understood (for some reviews see Hall 1998, Foster 1999 and Rosenberg 2001). At least two mutator genes (which code for DNA polymerases with high error rates) have homologues in eubacteria, archaea and eukaryotes.

The concept of investing in innovation by means of research and development under conditions of scarcity is well known to economists many of whom see it as the solution to environmental problems. Indeed, it is well known to all of us. In recent decades, rather than acquiring more fossil fuels, we have to some degree squeezed more mileage for our vehicles and heat for our homes per unit of fuel input by increasing the efficiency of cars and furnaces (a response to the energy crisis of the 1970's suggested by Lovins in 1976). Historically, for heating, wood became scarce and expensive. We moved to coal and successively to oil and to natural gas. In the human economic world, normally innovations which increase efficiency or change niches require some investment in research and development. Depending upon how *K*, the carrying capacity of the environment is defined, "R&D" can be thought of as a strategy for raising carrying capacity or for realizing capacity unutilised for what evolutionists call historical reasons. The necessary innovations were simply not previously available in the population. R&D is not prescient but neither is it entirely random -- it is normally focused on the relevant technology. Similarly, its success is not guaranteed; much of the investment goes for naught, but successes often make it worthwhile. That does not mean however that economic change is not an evolutionary process. For example, Nelson and Winter (1982) and Nelson (1996) include search processes, including for information, in their evolutionary model of economic change. It is not surprising therefore that although risky, natural selection sometimes favours genes or the expression of existing inducible genes that search for genetic solutions to difficult problems or take advantage of opportunities -- genes that, in effect, invest in genetic R&D. It hardly needs to be said that there is nothing "Lamarckian" about the phenomenon of adaptive mutation. Even if somewhat, although obviously never perfectly directed, (e.g. toward genes coding for enzymes in a biochemical pathway whose substrate is in short supply or toward those making organisms capable of utilizing a recently unutilised resource) mutator genes themselves must evolve by normal Darwinian processes. In eukaryotes, the logic of the evolution of such genes would be similar to that of genes for recombination i.e. genes which have their effect indirectly through other genes on which they then hitchhike. In the broadest sense, all of science is a form of R&D.

In a narrower sense however, it seems likely that, as well as favouring investing in the first "2M's", stalled progress should favour a 3rd M -- mutability, i.e. individuals with heretical tendencies or the expression of such, disposed towards breaking out of the mould of existing theories, methods, etc., in their research/teaching searching for ways to reach new goals or to break through historical obstacles to achieving existing ones.

4 Frequency Dependence: Avoiding Competition

To be favoured, normally the high-density strategies of maintenance, motility or mutability under discussion in the last two sections require what anthropologists call an uncircumscribed or unbounded environment (Ehrlich 2000:239 after Carneiro 1970). Such an environment is renewable, colonizable or with historically unutilised carrying capacity and hence crowding is only temporary, local, or niche-specific respectively. Maintenance is of no use if resources are not renewable; motility is of no use if there is not space available to move into; and mutability is of no use if there is no carrying capacity unutilised for historical reasons. However, ecological environments not only affect the strategies which evolve but are in turn affected by them, i.e. there are evolutionary and ecological interactions. Low densities favour growth strategies, which cause densities to rise depleting and degrading the environment. These high (temporary/local/niche-specific) densities in turn favour the spread of maintenance/motility/mutability strategies which do not so much cause densities to decline as they do carry population members to a time/space/niche in which densities are low favouring the spread of growth strategies once again.

Given that growth strategies do normally have direct ecological consequences in the form of depletion and degradation, it is not surprising that members of some populations, instead of evolving in response to density, evolve in direct response to the strategies present in the population, i.e. to what the others are doing. Rather than ecological optimization in the narrow sense, the principle is the game-theory one of negative frequency dependence. If some individuals (or all of them some of the time -- either at random or with some fixed probability) are engaging in primary research/teaching, then it pays others to do secondary research/teaching, to change topics or fields, or to innovate and vice-versa. This negative frequency-dependent principle is to avoid competition. Much science involves not so much the kind of intensely competitive race made famous by Watson (1969), as it does precisely avoiding such races: with A studying X, B studying Y, C studying Z etc. However, negative frequency dependence can be added to, rather than simply substituted for, density dependence. Under the simplest set of assumptions, at equal costs, pure density dependence predicts strategies should be present in proportion to density. These range from all growth at one extreme, through equal frequencies at intermediate densities, to all one or more of the 3M's at the other extreme. At equal costs, pure frequency dependence predicts the two should always be present at equal frequencies. At equal costs, combined density and frequency dependence still predicts equal frequencies at intermediate densities, but other equilibria are possible. For example at equal costs, with resources depleted by 20%, growth and maintenance/motility/mutability strategies should be present in a ratio of 2:1 [note 7]. In short, in science as in life, selection should be sensitive not only to the ecological environment but also to the social environment in the sense of what strategies others are pursuing.

5 Scale Dependence: Fast Specialists Versus Longer, Slower Generalists

Thus far it has been assumed that spatio-temporal boundaries are fixed (now versus then, here versus there, this niche versus that) and appropriate strategies have been considered. Now shift controls. Instead of assuming boundaries are fixed while energy content varies, allow boundaries to vary while energy content is fixed. Environments may differ because the same energy content is more concentrated or dispersed in time/space.

Resources may be devoted to doing research rapidly but for a shorter period of time in a field, yielding a higher rate (mass per unit time, so to speak) of knowledge. Alternatively, resources may be devoted to doing research at a slower rate but for longer (yielding knowledge over a longer time period). Biologically (but not sociologically), trade-offs between growth rate and time are well known. Mammals that develop more rapidly by many criteria lead faster, but shorter lives. "Live fast, die young" is the rule (Promislow and Harvey 1990). More familiar sociologically is the spatial equivalent. Resources may be devoted to doing research more intensively but in a smaller area of a field, (yielding a higher mass per unit area of knowledge so to speak) i.e. as a "specialist". Alternatively, resources may be devoted to doing research less intensively but spanning a larger area i.e. as a "generalist". Similar distinctions apply to teaching. Students with graduate degrees may be produced at short "interbirth" intervals or alternatively, at a slower rate but for longer. They may be produced in a single topic or alternatively, teaching effort may be spread more thinly but broadly across a wider range of topics. It was once thought that spatiotemporal properties of organisms including lifespan and size could be attributed to density. Now it seems obvious that they should instead be attributed to environmental scale. Organisms (and scientists) should evolve to be adapted to the spatiotemporal scale of environmental opportunities, whether small (narrow/short) or large (broad/slow but long).

Moreover there is a correlation between spatial and temporal strategies so that smaller organisms (e.g. measured in length) and more specialized tend to have fast life cycles, while the larger (measured similarly) and more generalized tend to have longer, slower life cycles. The reason for such correlations is not obvious. To attribute them to ecology simply moves the need for an explanation one step back. They may be attributable to cytoplasmic and other nongenetic forms of inheritance or to genetic correlations as follows.

Working rapidly (and by analogy) intensively is expensive in energy, i.e. in ATP or the mitochondria that generate it -- in theoretical economics, roughly labour power. Working more slowly, for longer may be more expensive in enzymes (tools), building blocks (inventories of supplies), ribosomes (protein factories), and mRNA (managerial knowledge and expertise) -- all in theoretical economics, roughly capital. Or to choose a technological analogy, Formula 1 racing cars are basically portable gas tanks (and small in area or volume) while vehicles that compete in long distance rallies carry tools, spare parts, repair manuals and so on (and are larger). In short, it may not just take a long time to grow large as has often been thought. It may also require a large area or volume to store all the things required to keep going for a long time. Hence organisms that cytoplasmically inherit more ATP or mitochondria themselves may have a material comparative advantage for both rapid growth and intense specialization. Those that inherit more "capital" may have such an advantage for both longer, slower growth and

generalization. Alternatively, the preadaptations may be genetic in which genes for the former complement and mutually favour each other while genes for the latter do the same. As is well known, selection is not just ecologically-dependent, but also own condition-dependent (including, but not exclusively, genetic condition).

Examples of such contrasts and their correlations are easy to come by in the history of science. Contrast contemporary examples of competitions with their narrow objectives to find the "gene for" whatever (which tend to develop and be concluded rapidly), with Darwin's work on evolution or even Hull's own work. The broad scope of the former is well known. So too is the length of time it took to complete. The scope of Hull's book is also truly vast in it are woven together a treatment of most major issues in the philosophy of science, the sociology of science, and evolutionary theory. According to the preface, his decision to study the systematics community sociologically was made in 1973 (although he probably became convinced of the relevance of the kin-selection concept to the sociology of science even earlier). While much of the material in his book appeared previously in journal articles, the entire package was not published until 15 years later in 1988. If the reasons for such correlations are endogenous, it means that scientists need to assess not only the scale of opportunities available in the field in which they are working but also their own suitability for different strategies. Are they personally more suited for fast, specialized races or for longer, slower work that is broader in scope?

There exists some sentiment that contemporary science is missing out on opportunities for the acquisition of knowledge in the form of too much support for specialized, short-term projects and not enough for broader, longer-term projects. However, in the past decade, there have been some moves in that direction. For example, Nature editorialized on the desirability of support for longer projects (Maddox 1993) and published a commentary decrying the loss of breadth in scientific education and practice (e.g. Greene 1997). The U.S. National Science Foundation moved toward longer, bigger grants around the same time (Mervis 1993). The applied message here is the importance of adapting science and its funding to the opportunities available in a particular field and to the different kinds of comparative advantage possessed by researchers rather than the intrinsic superiority of one strategy over the other. And of course evolutionary and ecological interactions and frequency dependence may obtain with scale-dependent strategies just as they can with density-dependent strategies. Fast specialists deplete small-scale resources but may give large-scale ones an opportunity to recover and vice-versa. If some are or are mainly, fast specialists, then it can pay others to be longer, slower generalists and vice-versa. It is also worthwhile to point out that given similar energy content in the environment, rate/density and time/space strategies may have similar payoffs, that is only on average. Concentrating as they do in small spatiotemporal ranges, r/d strategies represent high risk, high potential return alternatives (like market timing and stockpicking) while t/s strategies represent low risk, low potential return alternatives (like index funds). Scientists who are highly specialized and work rapidly in their research and teaching may hit the jackpot, but more commonly they come up empty-handed -- the variance in outcomes should be high. Not surprisingly given the emphasis on specialized, short-term research, there is some evidence that error rates in the published literature have been increasing since the early 1970's (Hawkins 1999). Choosing exactly what to specialize in and when to exhaust resources in working at high speed is a risky business. Generalists who work more slowly but for longer may be less likely to

make a revolutionary discovery, but they should also be less likely to come up empty-handed. The variance in outcomes should be lower.

6 Heterogeneous Environments: Flexible Strategies

Whether considering density or scale dependence, we have largely assumed that environments are homogeneous and hence so too strategy populations. Densities were either low or high not both, scale was either small or large not both. When we did admit of heterogeneity (introducing frequency dependence in Section 4), it was assumed to be endogenous to the system. For example, if densities changed from low to high, it was assumed to be because a growing population depleted resources; if they changed from high to low, it was assumed to be because maintenance/motility/mutability strategies carried population members to a time/place/niche in which they were plentiful again. However, environments can be exogenously heterogeneous -- with periods/patches of low and others of high densities for reasons unrelated to internal interactions within the system. Similarly, resources can be exogenously distributed on more than one spatio-temporal scale (fruit on trees, trees in stands etc.) Levins (1968) distinguished between fine and coarse-grained environments. Here the terms heterogeneous versus homogeneous will be used initially because heterogeneous environments themselves may differ in grain. Given a homogeneous environment, selection favours spending in several senses (e.g. whether on growth directly or via the 3M's, or whether r/d or t/s). Given a heterogeneous environment however, selection favours investing in morphological, physiological, and behavioural change/differentiation or phenotypic plasticity -- both of which for convenience can be lumped together as 'flexibility'.

It has long been known that development is a process not only of growth but also of morphological, physiological and behavioural change and differentiation. In individual development, life cycles pass through a sequence of stages and different kinds of cells, tissues and organs emerge, becoming different from each other -- processes largely achieved at the molecular genetic level through change and variation in control of gene expression. A genotype can give rise to individuals, each of which is internally heterogeneous in time/space. At the opposite extreme, on an evolutionary rather than a developmental scale, populations, species and higher taxa change and diverge from each other -- processes largely achieved through genetic change and variation. Between these, cyclical change can take place between generations in dual or even multi-generational life cycles (common in the complex life cycles of many parasites), and different kinds of individuals can become different from each other (morphs, genders, morphs within genders etc.). This between as opposed to within generations/individuals but still intrapopulation change and variation is sometimes achieved genetically -- gender differences in birds and mammals are genetic. Sometimes it is achieved through change and variation in control of gene activity. In many turtles and reptiles gender is phenotypically plastic. A genotype can give rise to heterogeneous generations/kinds of individuals (the former presumably by means of epigenetic inheritance mechanisms). In either the within or between generations/individuals case, heterogeneous environments favour flexibility -- which type being dependent upon patch size. If small, morphological, physiological or behavioural change/variation tends to occur within generations/individuals (change/differentiation) -- creating phenotypic checkerboards. If large, they can obtain between generations/individuals (phenotypic plasticity) -- creating a checkerboard of phenotypes. If uncertainty prevails but reliable signals are available,

change/variation of either kind may be condition-dependent. Gender differences in many turtles and lizards are dependent upon environmental temperature. Investing in flexibility is favoured in heterogeneous environments because normally specialist stages/structures are more efficient in the range of a niche they specialize in than are generalists in that range. Presumably the cost of flexibility must initially be traded off against growth, i.e. there are fixed or set-up costs of switching/varying in order to adapt to a heterogeneous environment. Just as with growth versus the 3M's, under the right conditions, the advantages are more than sufficient to compensate for these costs.

Flexibility in scale that takes place both within (differentiation) and between (plasticity) individuals is illustrated by organisms with a branching architecture. Such architecture has evolved independently in organisms many times among the unicellular (some algae), the multicellular (some algae as well as fungi and plants), and the colonial. Colonies of many marine invertebrates in which the individual elements are multicellular animals develop such an architecture. It is found even among colonies of eusocial insect colonies as in polygyne (multiple queen) fire ants (*Solenopsis invicta*). Supercolonies of these insects spread in the American south in vast branching networks in which individual colonies, connected by underground tunnels, arise by a budding process (Mann 1994). There is a large literature on possible evolutionary explanations of the growth habit and other features of branching organisms much of it on whether the function of branching relates to resources, antagonists or competitive interactions (for a discussion and references see Buss and Blackstone 1991). Here, for convenience, we shall assume resources are at issue.

The simplest of such organisms may be viewed as being composed of what, for simplicity's sake, we shall call and "laterals" and "leaders". A branching architecture is correlated with sessility and as mentioned in Section 3, where only laterals consume and hence the internal flow of resources is unidirectional, the function of leaders is to extend the organism's reach. Leaders can function as a form of motility in sessile organisms (Andrews, 1991). Often however, both laterals and leaders consume as in a fungal hypha; hence the internal flow of resources is bi-directional. Assuming equal profitability at equilibrium, the normally shorter laterals must be consuming a higher mass per unit area or volume (and presumably more rapidly), i.e. are more r/d selected. The normally longer leaders must be consuming resources through a larger area or volume of space (and presumably for longer), i.e. are more t/s selected. The entire organism is a mixed r/d and t/s strategist, adapted to more than one ecological scale. Despite the mixed nature of their strategy, individuals and populations do not necessarily devote equal resources to the two. If laterals arise frequently, which in turn, functioning as leaders, also give rise to their own laterals frequently the overall effect is a short but dense, bushy structure, a pattern long called "phalanx" like. This is still a mixed strategy, but one tilted towards the r/d end of the spectrum. Conversely, if leader(s) only give rise to laterals infrequently, which in turn, functioning as leaders, also only give rise to their own laterals infrequently, the overall effect is a long but sparse, tree-like structure, a pattern long called "guerrilla" like. This is still a mixed strategy, but one tilted towards the t/s end of the spectrum (for diagrams and examples see Andrews 1991, Buss and Blackstone 1991). Hence the same character can exhibit both kinds of flexibility -- differentiation within and plasticity between individuals.

Branching organisms are often constructed modularly whether somatically, reproductively, or both (whether severally or jointly). Somatic modules commonly arise from buds in the upper axes between laterals and leaders. These are a physical manifestation of resources invested in differentiation. They give rise to both leaders and laterals; they permit environmental exploitation to take place on more than one scale.

The parallel in science is clear. In heterogeneous environments, scientists can be called upon to not confine themselves to a single strategy. They may be required to pay the set-up costs of varying and changing among strategies -- working on one project in one way and another in another way. At various times and places they may be required to engage in both primary and secondary research, in primary research and changing topics or fields, in being conformist and heretical, in working as a fast specialist and as a longer slower generalist -- even if there is likely to be an over-all emphasis on one or the other. Not only are such mixed strategies possible, in fields in which opportunities are available on more than one scale, such flexibility lies at the very heart of the scientific process. Scientists commonly describe what they do in their research as reasoning from the specific to the general and from the general to the specific and importantly, believe that each complements the other. Philosophers are more inclined to talk of induction and deduction, or in more modern terminology observation and theory, with explanations emerging from their interaction (Kosso 1992). Such a formulation is consistent with what is observed in nature. Resources spent on maximizing the acquisition of specialized knowledge rapidly may yield a return which can be invested in the acquisition of general knowledge, over a long period of time. Science can proceed from the specific to the general and from the short to the long run. Equally, resources spent on the acquisition of general knowledge over a long period of time may yield a return that can be invested in the acquisition of specific knowledge, rapidly. Science can proceed from the general to the specific, and from the long to the short run.

Commonly philosophers argue that for circularity to be avoided in the scientific process, observations that nourish a particular theory should be independent of those used to confirm it. Hull builds his evolutionary sociology of science from a series of narratives about the history of biology and then tests it against evidence from the contemporary systematics community. Because observation is "theory laden" the requirement may be put differently: the theory used to support particular observations should be independent of the theory for which the observations serve as evidence (Kosso 1992, 155-8). However it is put, branching organisms proceed in such a manner. Hence laterals that nourish a particular leader are distinct from the laterals that the leader subsequently supports. The part of a leader that supports particular laterals is distinct from the part of the leader that the laterals subsequently nourish. Science, like branching growth, is an iterative process. In highly developed sciences, developing new subtopics or specialties (modules) capable of giving rise to both is one of the most valuable activities of all.

For heuristic purposes I slipped from scientists' "reasoning from the particular to the general and from the general to the particular" to philosophers' induction and deduction or observation and theory. I emphasize however that the original terminology more adequately expresses the evolutionary-ecological strategy distinction drawn here. That distinction is not the traditional philosophical one rather it is between specialized research performed rapidly, and more generalized research performed slowly but for longer. Empirical, theoretical, or methodological

research can be carried out in either style. The scientific literature is replete with theoretical research for example, mathematical models, of narrow scope and short lifespan.

At the same time, some caution is in order. There is something of a cult of variation and change in science today which from a bench perspective often appears to have more to do with the careers of administrators and the whims of granting agencies than with the real needs of research and teaching. Scientists and departments are told to change and distinguish themselves from one another. It sometimes appears to scientists that some days and places administrators want more research/teaching and others better research/teaching; some staying put and becoming established in a field and others pursuing the latest fad in topics, methods and theories; some being conservative and others radically innovative; some narrow specialists and others broad generalists. As long as the demand for such flexibility is imposed by real heterogeneity in the environment of research and education it should be profitable, but such change/variation does impose a fixed or set-up cost which, if unjustified, will detract from, rather than add to, the acquisition and dissemination of knowledge.

7 Conclusion

This paper has followed some principles of evolutionary ecology into some of the highways of the sociology and philosophy of science, not all of the byways. One major highway it has omitted is the whole complementary set of principles involved when evolution takes place in response to antagonists like predators and parasites instead of resources which, generally speaking, reverses things. For example if low densities relative to resources are conditions you take advantage of and high densities ones you flee, then the reverse is the case with respect to antagonists. How effort should be allocated between acquiring resources and defending against antagonists depends upon what densities, scale etc. relative to resources and relative to antagonists are, relative to each other. Science as a cultural activity has its antagonists. These include: pseudoscientists, extreme animal rights activists, and some creationists (which at times and in places it is wise to oppose). Additionally, throughout we have discussed ecological conditions and strategies appropriate to both individual growth (somatic functions, in science research) and demographic growth (reproductive or replicative functions, in science graduate and postdoctoral teaching). A second major highway omitted then is the relationship between the two r and K selection theory for example argued that low densities favour the latter and high densities the former. This is both a complicated issue in evolutionary theory and a contentious issue in science. Since in a sense it pertains to parent-offspring relations, it may be viewed as part of the sociobiology rather than the evolutionary ecology of science. In the future however, the evolutionary approach to science should be extended to the sociobiology of science including not only this, but also paper publishing and other forms of social interaction among peers.

The general principles of evolutionary ecology applied to science here are not the kind which are normally directly tested empirically in evolutionary ecology. Rather, they are general principles which logically must be true if the general theoretical framework, that culture, including that of science evolves adaptively, that it does so under ecological control, and that energy content, time and space (including niche time and space) are fundamental dimensions of ecological control. However, they do lead into a multitude of byways in which additional assumptions can be added, among which there are choices to be made, which therefore lead to different testable predictions.

While concentrating on highways rather than byways then, this paper has covered enough ground to make the case that introducing more evolutionary-ecological thinking into sociocultural evolutionism/memetics in general, and science studies in particular, is liable to be productive. Evolutionary-ecological concepts including density, scale, frequency and heterogeneity; appropriate strategies; and correlations among strategies including the role of comparative advantage suggest the direction in which explanations should be sought for such basic phenomena in science as primary and secondary research/teaching, changing topics or fields, and innovating; fast specialized and longer, slower more generalized research/teaching; avoiding competition; and the need for flexibility.

Notes

1. Actually there are more than two. These others include the adaptive immune response in vertebrates and learning by operant conditioning (Hull, Langman and Glenn 2001). However, most would also consider these "derived" evolutionary processes as Donald Campbell once called them -- programmed at least in broad outlines by biological/sociocultural evolution.
2. Strategies included in these tables apply similarly to the individual and the demographic. In addition to density/scale conditions relative to resources summarized in these tables, strategies can be favoured if at low frequency or if their user possesses a material/genetic comparative advantage (preadaptation) for them.
3. Fog's 1997, 1999 cultural r and K selection are different, mechanism-free concepts as he indicates, see (1999), Chapter 4.
4. How resources in the denominator should be measured depends upon the details. For predators, numbers of prey might matter most while for parasites, the size of hosts might matter most for example.
5. With simple inputs for which the decision to accept or reject can be made as a whole, it might be possible to acquire and excrete at low densities (likely using a single entry and exit) and to break down and build up at high densities. Commonly however resources are more complex and need to be processed for the decision to be made. In these circumstances low densities favour growth by acquiring and breaking down; high densities favour maintenance by building up and excreting.
6. See note 4.
7. This follows from a simple (linear) equilibrium model of density and frequency dependence. Assume that strategies of growth and maintenance/motility are present in frequencies of N and $(1-N)$ respectively at costs of C and $(1-C)$ respectively. Let E be the amount of resources which remain freely available in the environment and $(1-E)$ be the amount which has been absorbed into the population. For pure density dependence we set the product of the frequency and cost of one strategy divided by its total benefits equal to that of the other, i.e. at equilibrium:

$$(1) \frac{NC}{E} = \frac{(1-N)(1-C)}{1-E}$$

For pure frequency dependence the total benefits of one strategy are proportional to the frequency and cost of the other so that at equilibrium:

$$(2) \frac{NC}{(1-N)(1-C)} = \frac{(1-N)(1-C)}{NC}$$

For combined density and frequency dependence then:

$$(3) \frac{NC}{E(1-N)(1-C)} = \frac{(1-N)(1-C)}{(1-E)NC}$$

Appendix: r And K Selection Revisited

The mathematics of density-independent and density-dependent selection are not in doubt (see any ecology text). However, what they mean in the sense of what properties we should expect of organisms adapted to these different ecological conditions, particularly the latter, has been the source of some confusion. The eat versus (roughly) assimilate/search of foraging theory and the growth versus maintenance/motility of life history theory are, each on their own scale of course, essentially the same theory. They are also essentially the same theory as that of r (density-independent) versus K (density-dependent) selection. This is because the former alternative in each of the first two cases should be favoured under low (temporary/local) densities and the latter under high. However, they also make it obvious that there is no reason to expect that low densities favour small size and fast life cycles while high densities favour large size and long life cycles as the original interpretations of r versus K selection theory had it (Pianka 1970, 1999). If anything, initially they lead one to expect sizes and life spans to be negatively associated because of the trade-offs involved. Resources spent on growth cannot be invested in maintenance (similarly for motility) and vice versa. Ultimately of course, at equal costs and allocated under their appropriate conditions, sizes should be equivalent. Similarly, the parallel growth versus maintenance (or motility) distinction with regard to the production of offspring does not correspond, as is sometimes thought, to the distinction between more numerous smaller, versus less numerous larger offspring. Quality is quite simply quality, not quantity. It does however correspond, as is also commonly thought, to a high fertility regime versus one in which discriminating parental care (or provisioning of motility) permits a higher proportion of those fewer offspring that are produced to survive. Quality students do not know more, they know better -- their knowledge is better organized, contains fewer errors and as a consequence is more enduring/useful in other fields.

In essence, the original r versus K selection theory of what was to be expected under low and high density conditions did not distinguish between uncircumscribed and circumscribed environments and tried to explain the spatial and temporal characteristics of organisms by paying attention only to the energy content of the environment and ignoring its spatial and temporal features. In section 5, the problem of explaining why size and life span are commonly positively

correlated was addressed beginning with the concepts of small versus large environmental scale and rate/density versus time/space selection.

Stably low densities were thought to be unlikely because populations were expected to normally eat and breed their way up to the carrying capacity of the environment. Hence the original theory of *r* selection proposed that low or a history of unstable densities favour growth strategies. A population with a history of exponential growth punctuated by catastrophes was expected to be dominated by such strategies, which is reasonable. However, it also needs to be added, whether with reference to strategies of individual or demographic growth or both, that catastrophes of similar magnitude may occur with high frequency relative to period putting a premium on the rate of individual/demographic growth. Alternatively, a long period relative to frequency puts a premium on the time through which growth is sustained. Hence the distinction was drawn between *r* and *t* selection, attributable not to density but to (temporal) environmental scale. Similar distinctions apply spatially between *d* (density, i.e. in the sense of mass or numbers per unit area or volume) versus *s* (space, i.e. area or volume) selection. Ecological correlations between temporal and spatial scales, or alternatively, correlated comparative advantages (material or genetic) are what must explain positive correlations between life span and size -- whether physical or metaphoric, i.e. niche span and size. Scientists in their research and teaching, no less than organisms in their consumption and production of offspring, should evolve to conform to the spatio-temporal scale small versus large of resources available in their environment.

The original theory of *K* selection proposed that maintenance strategies were favoured at high densities or with a history of stably high densities. However, just as stably low densities are unlikely because populations are liable to eat and breed their way to the ceiling; stably high densities are unlikely because populations are liable to be eroded to the floor by their parasites and predators. On the other hand, just as catastrophes can strike growing populations, bonanzas can give a boost to declining ones. Hence it is reasonable to conclude that high densities or a history of instability in the form of bonanzas should favour maintenance strategies. Bonanzas of similar magnitude, like catastrophes, can take place with high frequency relative to period/distance, putting a premium on speed of motility/density of maintenance. Or they can take place with a long period/distance relative to frequency, putting a premium on the time/space through which such are sustained.

In addition to claiming that low densities favour growth strategies while high densities favour maintenance strategies (a form of which has been embraced here for uncircumscribed environments, although motility and in some cases mutability are also options), and that low density selected life cycles should be small and fast while the high density selected should be large and slow but long (rejected here explaining organismic scale requires concepts of environmental scale), the original theory of *r* versus *K* selection claimed that the low density (*r*) selected devote more resources to demographic growth (e.g. in science, teaching) while the high density (*K*) selected devote more to individual growth (e.g. in science, research). This question which can be viewed as belonging properly to the sociobiology of science is beyond the scope of this paper.

Finally on classical evolutionary ecology, r and K selection theory had nothing to say about the other half of the life history story beyond growth/some of the 3M's, i.e. about flexibility. Levins (1968) introduced the subject of evolution in changing/varying environments. Densities are not necessarily low because of catastrophes or high because of bonanzas -- they may be both at different times/places. The scale of environmental resources is not necessarily small or large -- resources may be distributed and utilized on more than one scale. Such heterogeneity calls for effort to be devoted to flexibility which itself may be fine (change/differentiation) or coarse-grained (phenotypic plasticity).

MEMETICS AND EVOLUTIONARY SOCIAL SCIENCE

By

Marion Blute

Department of Sociology
University of Toronto at Mississauga
marion.blute@utoronto.ca

Memetics is the scientific study of memes. The term “meme” was coined by Richard Dawkins (1976), suggestive of “m” for memory or imitation and “eme” for gene, for the basic unit of hereditary information or replication involved in cultural as opposed to biological evolution. Memetics became the subject of an academic journal (*Journal of Memetics - Evolutionary Models of Information Transmission*) as well as of more than half a dozen books (Aunger 2000, 2002; Blackmore 1999; Brodie 1996; Cullen 2000; Cziko 1995; Lynch 1996). According to some critics, memetics has joined extraterrestrial, exo or zenobiology as a science devoted to a subject matter whose very existence remains in dispute! However, those who view the meme concept as more amorphous or ambiguous than that of the gene have insufficient knowledge of biology. In those long molecules of DNA, the fact that none of the units of structure, function, replication and recombination coincide means that the gene concept is similarly ambiguous (for a useful review see Griffiths 2002). Of course one might then endorse abandoning the gene concept rather than adding a meme concept but in the age of genomics there is little chance of the former at least.

In one sense, only the term “meme” was new with Dawkins. For some time some social scientists studying a wide variety of phenomena including languages, science and technology, and economic organizations and institutions for example as well as theory in general had been applying a Darwinian-style evolutionary theory of “descent with modification” involving cultural transmission, variation and selection to their respective subject matters. Among memeticists, some difference of opinion exists over whether memes should be thought of as gene-like or virus-like but both points of view have made useful contributions to evolutionary social science.

The gene-like view. Social scientists tend to wonder whether they need a common term like meme across their various subject matters. It may or may not turn out to be useful in the long run but if nothing else, the gene-like concept of a meme has reminded us that cumulative evolution of complex entities requires digitally-encoded information. Social learning by ‘observation’ in a variety of sensory modalities can support a primitive form of cultural evolution as it does among chimpanzees (Whiten et. al. 1999) and Cetaceans (Rendell & Whitehead 2001) for example. However, only social learning by ‘instruction’, employing information encoded digitally in a string of symbols, among humans normally strings of phonemes or letters in sentences in a natural language, can a) support the inheritance of a large number of possible states (Maynard Smith and Szathmary’s “unlimited inheritance” 1995) and b) avoid the cumulative degradation characteristic of analogue systems (Dawkins 1995) and hence is required to support the cumulative evolution of complex sociocultural entities.

The virus-like view. The virus-like view of memes has usefully reminded us that much, even most cultural transmission in modern societies takes place horizontally rather than vertically

relative to genes. Social scientists have always been aware of this but have not paid sufficient attention to the implication that culture therefore evolves in a fashion that may be indifferent to its 'host's' biological fitness. Many memeticists emphasize that our culture, in fact, commonly parasitizes our biology. The "memplexes" that characterize membership in sects or cults, to cite an extreme example, often ruthlessly exploit the biology of their members, convincing them with mythical appeals to "family" to isolate themselves from their real families and dedicate their all to the survival and spread of the social identity of cult membership. This virus-like view suggests the application of basic principles of the epidemiology of infectious diseases (e.g. Ewald 2000) to culture to predict the conditions under which it will evolve to be benign or virulent relative to genes. According to those principles culture (like infectious diseases) with vertical transmission, a low multiplicity of infection, and infection by means of direct contact will tend to evolve to be more benign. By contrast, culture which is transmitted horizontally, with a high multiplicity of infection, and infection by means of vectors will tend to be more virulent. Assuming you care more about your biology than your culture (which is not necessarily the case - 'you' after all are a combination of both), practical lessons, particularly for teenagers, emerge from memetics. Listen more to mommy and daddy and less to your friends! Beware more of fads and fashions which can infect you multiply than of whole social identities like ethnic, religious and occupational identities. One of these latter normally precludes another and hence may be willing to leave something of your biology for itself to live on tomorrow! And finally, trust information conveyed personally rather than via mass media which, like insect-borne diseases, can get to you even when you are down and unable to circulate!

The future. According to evolutionary epistemology (Campbell 1970), universal Darwinism (Cziko 1995, Dennett 1995), or multi-process selection theory, selection processes are selection processes and the same general principles should apply whether realized biologically (gene-based evolution by natural selection), socioculturally (meme or social learning-based sociocultural evolution by sociocultural selection), or psychologically (neural-based learning by reinforcement and punishment) for example (Hull Langman and Glenn, 2001). Hence there is no point reinventing the wheel. For principles applicable to selection processes, memetics can benefit from a close study of evolutionary biology and related disciplines like taxonomy and evolutionary ecology. Taxonomy dealing with history, and evolutionary ecology dealing with selection are the two most important research programmes in biological evolution. Duthie (2003) in his pithy essay on the fork and the paperclip got it exactly right - the key questions are where did something come from and why did it evolve. Those who hope to make a contribution to memetics in the future require knowledge of one or more topics or fields in biological as well as in a social science discipline or disciplines. It has become well known whether by philosophers (Bunge 2003) or by granting agencies like the U.S. National Science Foundation that multi, inter and transdisciplinary research ("MIT" in science studies jargon) is where the breakthroughs are made.

This should not be taken to imply that the study of selection in other realms need be wholly derivative of the biological. There is much extant research but still much to be done in understanding the mechanisms of inheritance in sociocultural/memetic evolution (for an overview of social learning in animals see Heyes and Galef, 1996). There is much to be done in understanding how genes and culture coevolve in interaction with each other (Durham 1991 remains the most extensive treatment to date). There are many unsolved problems in biological

evolutionary theory and solutions to their analogues in the sociocultural realm could conceivably, in the future, feed back in the other direction. For example two important problems in the forefront of evolutionary biology today are the three-cornered relationship between evolution, development and ecology 'evo-devo-eco' and the problem of 'origins'. Everything which evolves under ecological control also develops under ecological influence and that includes the sociocultural. Artifacts and social identities for example not only evolve but also have a life course. Should the story and theory of life or culture in the context of origins therefore begin with a single 'juvenile' developing (implying that evolution developed) or with many 'adults' replicating (implying that development evolved) or somewhere else entirely?

Moving from recommendations to forecasting I think there is every reason to believe that the future of memetics/sociocultural evolution (understood broadly as the same enterprise) is bright. Many others think likewise (e.g. Mesoudi, Whiten and Laland 2004) although for reasons that I find difficult to understand, some still sometimes look with disfavour on the 'meme' word while freely using the similarly ambiguous 'gene' word.

THE CONSTRUCTION OF IGNORANCE AND THE EVOLUTION OF KNOWLEDGE

(Working Paper)

By

P. Bouissac

paul.bouissac@utoronto.ca

University of Toronto

During the last few decades, scientific research conceived as the empirical pursuit of truth and objectivity has been put on trial. For many, scientific knowledge has lost its prestige, integrity and quasi transcendence, and has come to be variously considered as a set of rival incommensurable theories similar to ideologies and religions, unstable configurations of power and authority prone to irrational changes, or even fabrications, fictions generated by self-delusion, if not deliberate deception. Landmark works in this critical process include Kuhn (1970),

Popper (1972), Feyerabend (1975), and Lakatos (1978): their criticisms have triggered many debates (e.g. Suppe 1977, Serres 1989) and have permeated our "épistémé" in more or less radical forms. Scholars from all fields have picked up the momentum and transferred these arguments from the natural to the social sciences, and, more generally, have questioned any intellectual endeavor inspired by the modern scientific ethos or modeled on the empirical method. The notion of knowledge as revealed or discovered truth has shifted toward a view which holds that knowledge is constructed, if not fabricated. Trivial versions of this new skepticism have filtered through the general population via the media, and, according to some, explain the marked decline in government funding for scientific research which characterized the 80s. In an article-manifesto, prominently published in *Nature*, two physicists, T. Theocharis and M. Psimopoulos (1987), called the attention of the scientific community to this state of affair, noting that the crisis of confidence had reached even the core of the scientific establishment itself and that this fact could be ominous.

They list the dangerous consequences which this critical movement might entail for society. Even if some aspects of their counterattack, which blends theoretical and pragmatic arguments, may sound naive at times, their warning should not be taken lightly, since, indeed, "skepticism and nihilism were not threats only in the remote past; nor do they now constitute a risk of only academic interest" (598). Confronting the issues raised by this epistemological debate is not only an intellectual challenge, but it also has political and ethical dimensions. Efforts toward a critical understanding of the scientific development of knowledge, including its sociological and rhetorical strategies, do not necessarily lead to a radical dismissal of its value and virtue. It may, however, help reassess its significance in the broader theoretical context formed by the interfaces which are presently developing between the humanities and the social sciences on the one side, and the formal and the natural sciences on the other.

1. Objects of perplexity

Knowledge has always an object. Prior to becoming an object of knowledge, was this object an unknown entity or agency? Is it instead a fallacy, a total or partial creation of knowledge itself? Are descriptions and explanations only means toward the fabrication of world views which legitimize political economies? Are experience and experimentations mere delusions, or do scientific methods of investigation yield the knowledge of universal laws which account for the qualities, quantities and behaviors of particular objects of perplexity which entice humans' minds into a quest for their knowledge? Or, are scientific institutions ways of building fictive objects on a grand scale, inventing problems and thriving on tax payers' money?² Or is science the patient and eventually successful confrontation of human intelligence with elusive objects, functions and laws whose discovery gives earthlings the power to act upon their environment and exactly predict the outcome of their actions?

Many of these questions have, at one time or another, inspired philosophical debates and political controversies over approximately two millennia of epistemological anxiety. They become all the more pressing in times of scarcity now that the scientific institutions specializing in the production of knowledge have developed close associations with military and economic power structures; contemporary society cannot afford to make hasty decisions because the stakes are so high that acting lightly in such matter amounts to playing Russian roulette. This is why, beyond the pure pleasure of theorizing, a reflexive enterprise focusing on these problems is in order.

Obviously, the first relevant question to ask bears upon the status of the object of knowledge. This issue has triggered intense discussions particularly in relation to experimental research (e.g., is the object an artifact?) and to the social sciences (e.g., is the object a function of the position of authority of the investigator?). Some problems in the latter domain will be now examined as a starting point for the argument I want to develop in this article.

One may ask for instance: Which method is most appropriate for reaching an accurate description and a satisfactory explanation of a socio-cultural object? This question suggests that, on the one hand, institutions and their productions stand as objects and that, on the other hand, methods are commodities among which a discriminating researcher can select the one which is best suited to the task at hand, given the assumed nature of the object. But such naive positivism tends to ignore the extent to which methods and objects are intimately associated, almost indistinguishable from each other like mutually definable correlates. Indeed, any method presupposes a model of its object, conceived in terms of the sort of information that the method is conceptually equipped to detect, if not to construct. Methodological strategies necessarily imply the elaboration of their object of inquiry within a more general conceptual scheme, and endeavor to determine the range of variables set forth by the model that is thus elaborated.

For example, analyzing public performances in general as acts of communication presupposes a pre-determined range of variables and their relations combined in a model. The model is the hypothesis which constrains the method as much as the method sets limits on the set of admissible models. The performance-as-communication model already contains the heuristic categories of commutable elementary units, syntactic structures and discursive strategies that the method will specify in accordance with the principles of functionalist and structural linguistics

and its theoretical extrapolations. In other words, the method makes the implied model of its object explicit and determinate, a process which may create the illusion that an autonomous domain of inquiry has been fully explored and revealed as a result of the judicious application of analytical procedures of a particular sort to some 'raw' material.

Is this to claim that all methods are equally valid or equally vain, and that the quest for knowledge proceeds through a forest of epistemological fantasies? Are researchers coming from various theoretical horizons doomed to confront one another in a conflict of interpretations? Is the cognitive interplay between models and methods necessarily condemned to be circular, thus locking researchers, individually or as groups, in epistemological solipsism? This is, of course, a possibility, and, as pointed out above, contemporary polemical debates, focused upon epistemological relativism, have called attention to the extent to which theories, scientific or otherwise, are parts of larger social, economical, cultural and ideological contexts which change over time under the pressure of sets of conditions which are so complex that they may appear at times as random and irrational processes.

However, the constant shifting of models or conceptual schemes does not suffice to justify the radical epistemological relativism of those who hold a purely 'historicist' view of knowledge (D'Amico 1989). It can be expected indeed that empirical information always exceeds the formal object of an inquiry; the method can perform its sifting and organizing functions only to a certain extent. The case can be made that there is a threshold beyond which the researcher can no longer ignore the accumulation of residue or noise. In spite of their inner beauty and logical consistency, models are eventually overcome by their insoluble surplus. Intellectual probity or a mere concern for pragmatic efficiency then motivates the restructuring of the initial model or the constituting of the residue itself as an object of inquiry with its own correlative model and method.

When the descriptive and explanatory power of a model is strained by the number of exceptions to the rules it generates or by the shrinkage of the domain of experience to which it applies, other attempts at modeling are undertaken. The challenge, however, remains to conceptualize the relationship among alternative or successive models, especially if it appears that the production of noise results from the very nature of models. The belief that socio-cultural phenomena can be exhaustively represented in terms of a unified theory may help one sustain the effort required to conduct systematic inquiries; but that remains a utopian goal.

Heuristic blindness can be productive only to a certain degree. The crisis of representation has brought to the awareness of many researchers the inherent artificiality not only of representational devices, but also of the objects which are constructed through representation along the investigative process, and which can acquire an inhuman dynamic of their own. This awareness can indeed take the form of a deep moral crisis when it turns out that human agents are thus objectified as 'others' and ultimately construed as mere tokens in some academic power game based on social predation. Ethnographic information can be indeed gathered as a mere commodity without consideration for the political conditions which make such an endeavor possible or for the consequences it may have locally.

The reflexive anthropology of the 1980s (e.g. Clifford and Marcus 1986,

Marcus and Fischer 1986) has forcefully voiced both ethical and epistemological problems that cannot be glossed over and are made all the more pressing at a time when anthropological pursuits, driven by the pressure of evolving geo-political circumstances, focus on the anthropologists' own society, and encounters most revealing challenges (Jackson 1987).

But where does epistemological despondency lead if not to a dark age of anomy, both intellectual and social? In response to the predicaments of knowledge, one may want to devise less arrogant approaches than the one with which positivism is usually associated.

2. The specter of the object

It is possible that the intractable problems resulting from a single, exclusive focus partly dissolve when frames and roles are systematically shifted. This alternative is at least worth exploring. The resistance to the constructed objects which manifests itself in the form of parasitic and haunting noise and the subsequent drifting of theoretical elaborations suggest some sort of refraction which calls for a spectroscopic approach.

Thus, hypothetical objects are not decomposed in terms of the analytical units or functions of a single model, but instead the targeted domain of experience is reconstructed in terms of differential, serial, and interfacial theoretical objects and subjects.

Interfaces may be relative, arbitrary, artificial and discrete to a degree, but they are nevertheless bounded within a continuum limited only by the horizons of experience. If, furthermore, these horizons are conceived as defined by the experience of a community of 'researchers' and 'researched' rather than by an individual's or school's point of view, a more comprehensive object of knowledge can be constructed that is at the same time complex, ordered and real. But before reaching this intellectual and moral grasp of an object that is both diverse and consistent, it is necessary to construct a multiplicity of interfaces. This approach might, of course, raise the specter of a fractal infinite regression, except that it does not intend to be exhaustive and can easily admit that interfaces are, to a degree, historically conditioned as the trans-object itself necessarily is.

A way of conceptualizing the complexity of a socio-cultural phenomenon as a domain of experience is indeed to model it as an array of interfaces without any suggestion of a principled hierarchical system. An interface is usually defined as a surface forming the boundary between adjacent spaces of whatever nature and consistency these spaces may be. Technically this surface equally belongs to the two contiguous domains but has also some of the properties characterizing each. The concept of interface can be further abstracted and recast in semiotic terms as the plane of contact between two systems modifying each other through some form of symbolic interaction. The contact between a liquid and a solid, which is one of the most striking examples of an interface, is only a particular case. There are also interfaces between magnetic fields as well as between deictic systems of signs such as those defining the boundary between two ethological territories. In fact all communication processes imply an interface between two or more information sources or fields. Interfaces may indeed overlap and probably necessarily do so. Social groups, marked spaces, fences, social distances, face-to-face interactions, spectacles

form interfaces whose correlated and synchronized modifications can be described as long as these interfaces are temporarily and heuristically construed as closed systems. All social realities can be seen as structured, or rather textured, by complex systems of interfaces on various levels of inclusiveness.

When particular interfaces are constituted as objects of inquiry, configurations of factors are put in place and hierarchical, or at least structural, orders define the objects of inquiry and determine their method. Both descriptive procedures and explanatory interpretations can then be developed in a manner congruent with the interfaces that have been thus constructed.

However, it must not be forgotten that artificiality, or rather 'artificiality', belongs indeed to the nature of interfaces. It would be misleading to conceive of interfaces as 'slices' cut through the 'real' of the institutions and their productions, and closely examined with a magnifying device as if they were biological tissue. The construction of an interface involves, on the one hand, the recognition of a zone of contact between two distinct domains and its methodological isolation and, on the other hand, the formulation of a hypothesis or model which determines which sort of information will be collected and organized as being constitutive of these conceptualized zones. This approach basically relies on a theoretical systematization of the natural cleavages of socio-cultural experience with respect to societies, groups, generations, sub-cultures, corporations, specialties, and so on. But these cleavages are so numerous, complex, multivalent, fractal, fluctuating and chaotic that any methodological determination of an interface can only be a grossly simplified model. However, building series of such interfaces may bring some measure of systematicity and coherence to the notion of 'thick' description which Geertz (1973) borrowed and adapted from Ryle (1971) and which seems to be the only possible response to the engrossing, overwhelming object that any socio-cultural phenomenon form as a domain of experience.

Thus, one may be led to conclude that it is not because an object of inquiry is constructed that the research process does not yield any amount of objective knowledge, as long as the construction process itself is taken into account and forms an explicit part of the knowledge thus acquired.

However, this perspective, which may help clarify the status of objects of knowledge as processed domains of experience, remains largely tautological and strictly pragmatic. A further questioning of the strategy at play in this process may contribute to a better theoretical understanding of the epistemological problems which are being addressed in the current crisis.

3. An architecture of holes, gaps and lacunae

Some fifteen years ago, Duncan and Weston-Smith (1977) edited a dense volume of collected articles under the tantalizing title *The Encyclopedia of Ignorance*. Prominent specialists - from Great Britain for the most part - in a wide array of scientific domains had been invited to write about the yet unanswered - or unanswerable - questions in their respective fields of inquiry. The resulting texts provide a most enlightening vista on the process through which knowledge is constructed in the sciences. Far from radiating unlimited confidence in their ability to conquer the unknown as if it were an object to be mapped, measured and packaged, the contributors to this volume carefully delineate their own area of ignorance and emphasize the crucial part that

this process plays in their pursuit. Each one relies on a particular rhetoric to express this essential absence of knowledge. For example, some evoke a daunting horizon of increasing complexity, some wonder whether the human brain can cope at all with this complexity beyond the requirements of extended survival strategies, some even question the very possibility of knowledge.

For instance, Lehman, a computer scientist, declares in conclusion of his contribution: "Total knowledge, the final state, can never be reached. Ignorance must always be present" (354). This should be understood not as a romantic declaration but as a technical, almost clinical constation. It raises an interesting question regarding cognitive and discursive strategies through which scientific knowledge is constructed. Usually, the cumulative process of science is metaphorically apprehended as a 'positive', ever increasing sum. However, it also could be conceived as the 'negative' - in the photographic sense of the term - of an activity geared toward the relentless construction of ignorance, an architecture of holes, gaps and lacunae, so to speak. This might sound paradoxical, but The Encyclopedia of Ignorance reveals a consistent strategy which consists in conceptualizing what is not known, not in a vague, open-ended manner, but with application, precision, almost industriousness. It appears that the exercise did not seem strange to these scientists for the good reason that setting up what could be called "stages of uncertainty" is the very stuff of their professional existence. If, indeed, knowledge is information, its condition of existence and its real measure is uncertainty, and therefore depends on the construction of ignorance. There is no possibility of information if there are no alternatives with various degrees of probability. The more unexpected, the greater the discovery; because the uncertainty is resolved by a choice, which was not ever seriously, taken into consideration when the most probable alternatives were laid out in the experimental design. Such discoveries suddenly cause a reframing of ignorance because alternatives previously considered to be equally probable in view of a given knowledge become improbable and, thus, the presupposed knowledge which had led to this state of affair must be retroactively discarded and replaced by new questions which redefine the horizon of ignorance.³

Naturally, "science" or "scientific knowledge" as an entity is a rhetorical device. A grammatical subject which obfuscates the politics of institutions, somewhat like "life" covers the swarming and teeming of myriads of competing organisms. Academic disciplines themselves are dramatis personae on the political stages which appear whenever a critical mass of researchers agree on the definition of a domain of ignorance and on 'legitimate' methods to perpetuate this ignorance by a constant renewal of the stage of uncertainty. It should be clear at this point that 'ignorance' is not taken here in the absolute sense of self-ignored ignorance, i.e. an absence of knowledge caused by the absence of a stage of uncertainty in the representational system of an organism. The ignorance to which it is referred here is more akin to the state of knowledge of a sleuth whose reasoning is portrayed at the beginning of a crime fiction than to the situation of someone who would have been always immersed in total darkness. Scientific disciplines need decidable uncertainties but need them forever, so that the narrative will continue.

State of the art articles as a genre always are structured by what could be called a dynamic of lack. The Khunian paradigms need solvable but indefinitely expanding puzzles. In as much as these puzzles are expressed in the form of discourses, they are rhetorical artifacts. But, by contrast with the

Humanities and some sectors of the social sciences which thrive by staging undecidable uncertainties, the empirical sciences construct decidable ones by specifying in each case what will count as information, and which new ignorance this information will help formulate. From a general point of view, it seems impossible to conceive of a discipline which would consist of the mere transmission of a completed knowledge. A discipline which would fail to generate information, i.e. which would have exhausted its capacity to construct ignorance, would quickly disappear. The necessary dynamic must come from the construction of a relatively determined lack of knowledge. Therefore disciplines can be viewed as generators of uncertainty and can be compared with each other from this point of view. As it has been hinted above there are many forms of ignorance depending on the generator's model. Each discipline seems to be based upon a different blueprint, or a program (in the computer sense of the term) which specifies how to construct its sui generis uncertainties. But such programs are necessarily in competition with each other because they need hardware (i.e. human and economic resources) in order to be implemented.

An illustrative case is semiotics, a discipline-to-be which did not succeed in achieving disciplinary status, although it developed a dynamic toward this goal. It is symptomatic that the two 'founding' programs, i.e. those of Peirce and Saussure, essentially consist of discursive fragments about some unknown to be discovered; both evoked a relatively well specified horizon of ignorance but fell short of determining with optimal quality the generative model which could have yielded a self-replicating puzzle. As a result, the stage of uncertainty which defines semiotics remained populated by undecidables which can generate indefinite discursive productions, but finds themselves in competition with more powerful programs of uncertainties such as those of philosophy and literary interpretation. This state of affairs is appropriately expressed through the convoluted rhetoric of undecidability in the concluding paragraph of an essay by a representative semiotician: "A final remark, which is for obvious reasons inconclusive: From the preceding propositions one might get the impression that this program of enquiry will result, all in all, in a referential tautology. Well, it could also be said - precisely! Giving due regard to what M. Eigen (1975) has stated at the outset of his influential article on "Evolutionary Games", let us take in, henceforwards [interdiscursively] the basic rule of reconstruction as he puts it: "The origin of life [intertextuality] is tautologous with the origin of biological [textological] information." Therefore, ours the task, may be eternal." (Ruprecht 1991:73)

It is, indeed, undoubtedly so, but by design rather than because of an epistemological curse, as post-modern romanticism would have us believe. Naturally, "design" is taken here in the sense of "structural feature", and not psychological intentionality.

The same process of constructing a form of ignorance is observable across the whole array of modern disciplines which are thus provided with the dynamic needed for evolving and persisting over time. But each discipline is defined by its particular rhetorical strategies and modalities of implementing the perpetual reconfiguration of its stage.

At this point, one may be inclined to conclude, as some do, that knowledge production is a mere rhetorical trick, that special terminologies are ways of obfuscating tautological statements, and that the notion of scientific progress is nothing but an ever changing narrative used to legitimize

an otherwise frivolous game of power and confrontations. However, an argument to the contrary can be extrapolated from evolution theory - not as a dogmatic derivation but as a way to account for the fact that, indeed, some forms of constructed ignorance and the information it yields often make a difference for the organisms engaged by this process.

Let us recall that evolutionism is, briefly, the theory which holds that selection operates on random variations. It is a non-teleological process. Adaptation is not conceived as a goal-oriented change but as a serendipitous advantage yielded by a particular transmissible modification of an individual phenotype. For an advantageous variation which contributes to evolution, there are countless detrimental ones leading to early elimination of those genotypes from the genetic pool. Moreover, what is advantageous in a particular environment, can become a liability in a different one or if the initial environment changes. At the cost of a metaphoric translation, strategies which elicit information can be conceived as phenotypes implementing genotypic variations whose outcome may, at times, confer a decisive advantage through a close fit with environmental constraints. There are actually no good reasons for excluding rhetoric from the domain of natural phenomena, nor for explaining it in merely functionalist terms.

But, having set the theoretical perspective which will be further discussed in the next section, let us return for a while to the strategic construction of ignorance and let us examine what 'constructing ignorance' practically means. It consists of building a model, generally of an interface, such that some relations constitutive of the model remain indeterminate. For instance, in Duncan and Weston-Smith (1977), Barlow, a specialist of physiological optics, addresses the topic of the languages of the brain: "The language for communication between the various higher parts of the brain must use symbols with an agreed meaning, for otherwise one part would not understand what another part said. We do not know what these symbols are, nor how their meanings are agreed to. However, the material discussed in this essay does enable us to hazard a few guesses about the general nature of the language, and here are three of them. (1)

Whatever a symbol may correspond to in the external world, internally it is likely to be represented by nerve impulses in a nerve cell or in a family of nerve cells, for we know of no other tokens that can be rapidly exchanged between the parts of the brain. (2) There is nothing to indicate that these internal symbols occur in a single serial string [...]" (271-271). This suffices to make clear that the model construes "part of the brain" as agencies which interact through communication, i.e. transfer of information; while there is evidence that such interactions occur, the mode of communication is not known. This uncertainty is, however, reduced to a few alternatives which are introduced as the stage of uncertainty within the model itself. The narration is familiar: the sleuth has evidence that two conspirators communicate through a secret code. Since they live in different cities, the messages have to be carried. By whom and in which form are these messages transmitted? and so on. This was the state of the art fifteen years or so ago. Neurotransmitters are now better known, but this new knowledge creates its own horizon of uncertainty.

4. Epistemology: from creationism to evolutionism

It seems that, at this point of the reflexion, at least two assertions can be stated which would be supported by a reasonable consensus. First, the process of scientific observation necessarily

implies some form of theoretical presuppositions, hence the logical pre-eminence of theory over scientific observation and experimentation. This argument has been put forward and convincingly argued by Popper (e.g. 1972:340-361) and the counter argument that theories can be made obsolete by disproving data does not establish the reverse. It simply shows that a theory can be replaced by another. This leads to the second assertion, namely that theories are entities in competition with each other. Some are short lived or remain confined to a small circle of minds; others spread among much larger groups of thinkers, researchers, and teachers; some gain the status of worldviews, or commonsense, by taking hold of whole populations. The paradigm shifts described, but not explained, by Kuhn, dramatizes this eliminative process by evoking some "irrational" forces.

If it is true that, as has been suggested by the argument developed in the second and third sections of this essay, theories are differentiated ways of constructing uncertainty, and correlatively, of producing information, it could be concluded that they share an important, if not critical, feature with living organisms. This line of argument draws from current assumptions made in artificial life (AL) research, holding that the "logical form" of an organism can be separated from its material basis of construction, and that "aliveness" will be found to be a property of the former, not of the latter" (Langton, 1991:11). The way, in which theories come and go, prosper and disappear, indicates that, although they are generally considered to be produced by human brains, they are endowed with a relative degree of autonomy with respect to the populations of organisms among which they spread with various degrees of success. Traditional philosophies and religions have developed an ontology of ideas, narratives, instructions and rituals which take such autonomy for granted (e.g. Plato's ideas; divine words embodied in sacred texts; rituals identified as divine beings in Hinduism). Moreover, secular poets, philosophers and scientists have often referred to the sui generis dynamism of ideas or theories as quasi agencies independent from their own psyches.

Metaphorical expressions in many languages emphasize this puzzling impression: one comes across an idea, one may yield to the power of a worldview or a system, one may be inspired, possessed, turned on by a theory, and so on. Considering the way in which myths seem to unfold and transform their structures as they drift across continents from population to population, Levi-Strauss once noted that "The Ojibwa Indians consider myths as 'conscious beings', with powers of thought and action" (1969:12, note) and claimed that his goal was "to show not how men think in myths, but how myths operate in men's minds without them being aware of the fact. (ibid:12) Someone can also identify with a particular theory and passionately fight for it - many humans have died for a worldview and still do - and, sometimes, can as easily switch to another one without noticeable detrimental effect on his/her organism and mental life. Ideas, faith, commonsense, belief can be shown to share features with theories, even to be theories under other names. Theories have no particular regard for the welfare of the populations among which they may thrive. They may even conceivably go extinct because "their" population disappears, precisely because of some ill effects of the normative behavior they consistently promote in the population. On the other hand, some theories may have some long term beneficial side effects on "their" populations. But it does not seem that as an information structure a theory as such could have either a benevolent or malevolent intent. It simply spread as fast and as much as possible, eliminating competing theories in the process, sometimes softly by causing them to be forgotten, sometimes violently by physically suppressing the populations which hold them.

Naturally an extended metaphor cannot be used as an argument. Common sense associates theories so closely to the mental lives of their generators that such evolutionary analogies probably will be considered as nothing but playful speculations. However, it could also be pointed out that this perceived indissociable association, this identity of an information-producing structure and the brain which implement it, might be just a theory among others. But, then, it might be opposed to this line of thought that, according to a well known principle, one is not entitled to demonstrate a theory by this theory itself, except of course if this new theory had such a powerful information producing structure that it would "entropize", so to speak, Gödel's argument.

The notion of evolutionary epistemology goes back to the end of the 19th century. But its development remains anthropocentric. The survival rate of theories depends on their usefulness to humans; in fact they are closely related to the fitness of particular individuals. They are part of the phenotype. Popper, however, who discussed the issue on several occasions (e.g. 1972:65-70) perceived the inherent problems attached to this view: "[...] questions of truth or validity, not excluding the logical justification of the preference for one theory over another (the only kind of 'justification' which I believe possible) must be sharply distinguished from all genetic, historical, and psychological questions. [...] logical investigations of questions of validity and approximation to truth can be of the greatest importance for genetic and historical and even for psychological investigations. They are in any case logically prior to the latter type of question, even though investigations in the history of knowledge can pose many important problems to the logician of scientific discovery". (1972:67-68).

This is a way of saying - albeit from another theoretical viewpoint than the one proposed here - that organisms and theories are entities of different order. But the order which is constitutive of Popper's theory implies a hierarchy whereas "order" will be taken here in its taxonomic sense.

Although the evolutionary selection metaphor applied to theories appears often in the epistemological literature of the last two decades, it is not until the bold, albeit tentative introduction of the concept of "meme" by Dawkins (1976:206) that a new way of thinking evolutionary epistemology could be proposed. Let us recall the initial, somewhat awkward formulation of this hypothesis: "Just as genes propagate themselves in the gene pool by leaping from body to body via sperms or eggs, so memes propagate themselves in the meme pool by leaping from brain to brain via a process which, in the broad sense can be called imitation. If a scientist hears, or reads about a good idea, he passes it on to his colleagues and students." The term "meme" was somewhat playfully coined after the French "même" for "same" and with phonetic allusions both to "mimetic" and to "gene". In the paragraph following this introduction of the new concept, Dawkins quoted the summary that one of his colleagues, N.K. Humphrey, produces in reaction to the reading of an earlier draft of this chapter: "memes should be regarded as living structures, not just metaphorically but technically. When you plant a fertile meme in my mind you literally parasitize my brain, turning it into a vehicle for the meme's propagation in just the way a virus may parasitize the genetic mechanism of a host cell. And this isn't just a way of talking - the meme for, say, "belief in life after death" is actually realized physically, millions of times over, as a structure of the nervous systems of individual men the world over." (207) In his subsequent publications Dawkins returns to the concept of "meme" (1982: 97-117, 1986:158)

and indicates attempts made by others to develop his hypothesis (e.g. Delius, 1990) which has also been taken up since by Dennett (1991).

The idea of entities endowed with both genotypic and phenotypic structures independent from the biological ones but evolving in a parasitic relation to them, remains an intriguing and fascinating metaphor which shatters our world view as if it were an aftershock of Darwinism but is too "odd" to be taken seriously. Dawkins himself has been cautious in his subsequent and brief treatments of the "meme" idea, as if he were daunted by the full implications of this emergent theory. It is worth noting in passing that "memes" are strikingly different from the "culturgens" conceived by Lumsden and Wilson (e.g. 1981:27, 368) which remained modeled on functional artifacts and the process of cultural inheritance. Even Boyd and Richerson (1985) for whom "culture is a system of inheritance [...]. Today's cultural traditions are the result of cumulative changes made by past and present bearers of them" (20), shy away from the full implications of Dawkins' views. They state: "Our definition of culture is not at all specific about the nature of the information that affects phenotypes. In particular, we do not assume that culture is encoded as discrete "particles [...]. Relatively little can be said on this topic since our knowledge of the neurophysiology of social learning is primitive compared to our knowledge of the molecular biology of the gene" (37). However, when they address the issue of "horizontal" transmission, i.e. transmission within a generation rather than across generations, the analogy with parasitic phenomena naturally comes to their minds: "Horizontal transmission is analogous in some ways to the transmission of a pathogen [...]. The item of culture being spread horizontally acts like a microbe that reproduces and spreads rapidly because it is "infective" and has a short generation length compared to the biological generation length of the "host. Fads and fashions and technical innovations are familiar examples". (8) The epidemiological metaphor is also used by Cavalli-Sforza and Feldman (1981) in their quantitative study of cultural transmission.

As long as the metaphor is constrained by the model of a biological parasite such as a bacteria or a virus, the analogy remains tantalizing but non-operational. This seems to be the source of Dawkins' reluctance to proceed further with his yet undeveloped "meme" theory. However, another analogy may come to the rescue. A developing sector of computer science focuses on information structures whose behavior within computer environments resembles so much the behavior of viruses within a biological milieu that the concept "virus" or its colloquial, more benign form "bugs" has gained wide currency, and has become the object of intensive scrutiny. Cohen (1990, 1991) has fully explored the issue and interestingly emphasizes that, although computer viruses have become associated with malevolent intent in the form of criminal or mischievous artifacts, they are, like their biological equivalent, two-edged swords: "the features that make computer viruses a serious threat to computer integrity can also make them a powerful mechanism for the reliable and efficient distribution of computing resource" (199:23). But this is not all; not only are computer viruses subject to mutations, but also some of these mutations may happen to be beneficial as Cohen shows with the case of the Morris' Internet virus. The point which seems to be most relevant here is that computer viruses can provide an operational model for "memes" conceived as programs endowed with their own dynamism, albeit of a non-biological nature (see Langton 1991, mentioned earlier). It is therefore possible to conceptualize theories, under any other names, as information structures (hence the centrality of uncertainty in the dynamics of their implementation), whose relation to the environment within which they

replicate is double-edged. In the same ways as a genetic random mutation may by chance yield an advantage for the organism which carries it as a part of its phenotype, an information structure variation (which can be a copying error, a misunderstanding or a misspelling) can spread through a population both horizontally and vertically and yield an advantage (adaptability) for this population. This theoretical view, which seems to provide a first step toward a truly evolutionary theory of culture, could explain many features of cultural and scientific evolution: why cultures and knowledge are only relatively cumulative; why cultural traits are not necessarily beneficial to the populations within which they thrive; why theories constantly displace each other but sometimes make temporarily irreversible differences in terms of the survival of the populations which carry them. The perspective which is thus opened might succeed in "displacing" or "entropizing" the creationism which remains implicit in traditional theories of knowledge, whose current crisis may represent a conflict of evolutionary significance.

EDITORIAL: MEMES MATTER

By
Paul Bouissac

This editorial appeared in Volume 5 (2) of *The Semiotic Review of Books*

Although the *meme* hypothesis has been around for quite some time - it was first proposed by Richard Dawkins in 1976 - it does not seem to have had any decisive impact yet on the speculations and investigations of semioticians. There are notable exceptions such as Koch (1986) or Delius (1990), but they remain marginal in the field of semiotic theory. Some disciplines have sporadically taken notice of Dawkins' idea either to dismiss it as "nothing new" (Costall, 1991) or provocatively champion it by developing its full metaphoric potential (Dennett, e.g. 1990). Others have tried to operationalize the concept within the domain of evolutionary biology (e.g. Bonner, 1990). However, its novel, counter-intuitive implications deserve more serious considerations in the broader epistemological context of a variety of contemporary advances both theoretical and empirical. As has been often the case in the history of scientific knowledge, an idea may inconsequentially float around for some time until it connects with other concepts or methods, usually apparently unrelated, to eventually precipitate, so to speak, and drastically change the way in which humans perceive their environment and themselves. Is the *meme* hypothesis of such a kind?

Let us recall the initial, somewhat awkward formulation of the meme hypothesis: "Just as genes propagate themselves in the gene pool by leaping from body to body via sperm or eggs, so memes propagate themselves in the meme pool by leaping from brain to brain via a process which, in the broad sense can be called imitation. If a scientist hears, or reads about a good idea, he passes it on to his colleagues and students" (Dawkins 1976: 206. The term "meme" was somewhat playfully coined after the French "Meme" for "same" and with phonetic allusions both to "mimetic" or "memory" and to "gene." In the paragraph following this introduction of the new concept, Dawkins quoted the summary that one of his colleagues, N.K. Humphrey, produced in reaction to the reading of an earlier draft of this chapter: memes should be regarded as living structures, not just metaphorically but technically. When you plant a fertile meme in my mind you literally parasitize my brain, turning it into a vehicle for the meme's propagation in just the way a virus may parasite the genetic mechanism of a host cell. And this isn't just a way of talking - the meme for, say, "belief in life after death" is actually realized physically, millions of times over, as a structure of the nervous systems of individual men the world over (as quoted in Dawkins 1976: 207).

In his subsequent publications, Dawkins returned to the concept of "meme" (1982: 97-117, 1986: 158, 1989: 322) and indicated attempts made by others to develop his hypothesis (e.g., Delius 1990).

Until now, the idea of entities endowed with both genotypic and phenotypic structures evolving in a parasitic relation to the organism whose brains provide them with a vital environment, remains an intriguing and fascinating metaphor which shatters our worldview as if it were an aftershock of Darwinism, but it may seem to be too "odd" to be taken at face value. Dawkins

himself has been cautious in his subsequent and brief treatments of the "meme" idea, as if he were daunted by the full implications of this emergent theory. However, in the context of the changing epistemological landscape of the 1990s, this reconceptualization is being given new dimensions by a range of recently developed concepts, such as computer viruses (e.g., Cohen 1990; Delius 1990) and artificial life (Langton 1992), which provide a quasi-operational context for the speculative manipulation of this new idea (Bouissac 1992). For example, advances in the understanding of self-replication as an emergent property arising from local interactions in fairly simple systems (Reggia et al. 1993) 'suggest a possible avenue for a formal, canonic description of memes.

However, strong resistance to this approach, ranging from amused disbelief to philosophical arguments - mostly drawing from the long standing controversy concerning intentionality (e.g., Costall 1991) - has transformed a seemingly playful suggestion with which eccentric minds would toy into a potentially dangerous frontier of science, as if the Darwinian theory of evolution were bracing for a renewed confrontation with the last defense line of a long-established worldview order dominated by dualism (Bouissac 1991).

Along the line of Dawkins, "memes" will be taken here as informational structures, or sets of instructions, endowed with their own dynamism (autopoiesis) and constrained by the same evolutionary laws as genes, but their biological status will be more specifically ascribed to parasitism both in the predatory sense-- as N.K. Humphrey first visualized the idea (see quotation above) - and the symbiotic sense, along the line of the developing paradigm of symbiogenesis (Khakhina 1992).

But a note of caution is in order. In dealing with such problems, it is obvious that the *heuristic* status of the meme-as-parasite hypothesis should be emphasized even if some scientifically established data and currently accepted theories are brought into the argument. All too often, the humanities in the social sciences have borrowed ideas out of context from the natural and empirical sciences and have generalized them in the form of all-purpose metaphors of little descriptive value, such as the notion of social Darwinism or the right/left dichotomization of cerebral functions. An exploration of the meme hypothesis should try to avoid such pitfalls by a constant concern for the falsifiability of the propositions it may come to formulate. At the very least, the relevance to semiotics and to the social sciences of the issues potentially addressed by the meme hypothesis must be acknowledged, and even if the conceptual exploration sketched here proves to be misguided it might help better define the limits and pertinence of this challenge to established wisdom.

In as much as memes depend on other organisms for sustenance and reproduction (replication), their survival is bounded by the lifecycle and reproductive success of their hosts. As bearers of brains which afford the conditions necessary for memes to spread through replication, *Homo sapiens* is a vital resource which is itself dependent upon predation and other environmental commodities for the species' evolution and maintenance. Moreover, *Homo sapiens'* biological mode of survival involves a high degree of motility and dispersal. Therefore, memes can become extinct for the same reasons as parasites. An examination of the life conditions of parasites thus sheds some heuristic light on memes' modalities of existence.

Typically, parasites are dependent upon patchy and ephemeral resources because the other organisms - plants or animals - which are their hosts are themselves scattered over large areas and are not constant over time. The feeding specialization of the hosts compounds with the feeding specialization of the parasites, which is often extremely narrow. In addition, a parasite's life-cycle often requires more than one host, thus increasing the complexity of its reproduction, mainly if stages in the parasite's development must match stages in the hosts' lives. Since many parasites themselves use other parasites as hosts, it should be obvious that trophic and reproductive constraints make parasites' survival more complex than is the case for free-living predatory organisms, which depend on a much larger array of feeding resources and whose reproductive process is more flexible. As a result, parasitic species can never reach a state of equilibrium with their environment (i.e., their hosts) unless their parasitic mode of life evolves towards mutualism or even symbiosis. Another remarkable result of the parasitic mode of life is that ecological and genetic factors constantly interact to form within a given species "a patchwork quilt of genetic incompatibilities between closely adjacent populations" (Harper 1977: 412). Low probability of colonization and high probability of extinction in patches are among the consequences of the above properties of parasitic species (Price 1980: 77). In response to such ecological constraints, these species have evolved a variety of reproductive strategies such as an extreme longevity, including in some cases extended resting stages - up to several decades - which can combine with various sexual and non-sexual modes of reproduction such as mating before dispersal (colonization), self-compatible hermaphroditism or parthenogenesis.

There are obvious homologies between some of these strategies and what can be observed in the case of memes, namely the clonal mode of reproduction and the reliance on extended resting stages in the form of inscriptions - using a variety of semiotic systems --stored into non-organismic supports. These periods of latency, which enable memes to bridge the gaps occurring in their vital resources, do not constitute however an absolute warranty of survival since, as in the case of parasites, they depend upon coming across an appropriate host at least within the period of time during which the physical support ensures their conservation.

Another important factor to be considered is that memes cannot be confused with evolved, wired-in, adaptive behavior. As any parasitic organisms, their biological dynamic exclusively concerns their own replication - in this respect they are strictly "selfish" to use the metaphor that Dawkins applied to genes - and consequently are neither detrimental nor beneficial to their hosts by necessity. In the same way as random genetic variations sometimes turn out to be adaptive, thus causing evolution to occur. Memes can both be aleatoric and occasionally generate in their hosts behavioral modifications which are adaptive (Bouissac 1992). However, meme-driven cultural habits may be only relatively adaptive with respect to a temporary subset of conditions, and may happen to be devastating in the long run. Historical time must be always measured against evolutionary time when assessing cultural changes. However, some memes may afford an adaptive advantage which improves the reproductive success of *Homo sapiens* genes. The reverse can naturally occur and some memes can become extinct because their own success in replication causes the extinction of their hosts. It must be remembered here that their hosts form a patchy and ephemeral resource and that resting stages are not immune to total destruction (viz. the burning of ancient libraries).

If memes are indeed a crucial factor in the emergence and evolution of cultures, the latter's patterns of patchy development and eventual sudden or slow extinction are compatible with an important consequence of the parasitic mode of life: namely the impossibility of reaching a state of population equilibrium (Price 1980: 44-52).

Beside the death of the host - or the extinction of its species - caused either by the ill-adaptive effects of a meme or a combination of memes, or by other factors, memes can for reasons other than those relating to their parasitic mode of survival. At least three such causes can be considered: changes in the environment, intrinsic fragility, and elimination by other strains of memes. These are general evolutionary conditions applying to all forms of life organic or not (Langton 1991).

As any organism, memes cannot be conceptualized independently of their environment. Adaptation by selection upon both genetic and memetic variations operates with respect to environmental factors. Catastrophic changes in memes' environment, that is the brain or a particular anatomical, physiological or chemical component of it, may eradicate a meme population, or trap it in a dead end without possibilities of further replications.

Another factor which must be taken into consideration when assessing the conditions of survival of memes is their intrinsic structure and degree of complexity and specialization. Complexity entails fragility not only because of a closer dependency on environmental conditions but also because of a higher risk of replication errors. These two factors may compound to drive memes to extinction. An ad-hoc example of the latter could be some secret formulae of ancient medicine or medieval alchemy. Selective secrecy and exclusively oral replication - i.e., absence of resting stage - can be intrinsic components of a meme's set of instructions and thus account for its built-in fragility. It can be hypothesized that some memes do not survive beyond a small number of replicative generations. The argument of Dawkins according to which longevity is a criterial feature of memes seems to be hardly defensible. With respect to evolutionary time, how can longevity be measured? Even a pattern of information which would replicate only once would qualify as a meme because of this very property which has been thus demonstrated. A meme is no more necessarily a successful meme than a gene is. Unsuccessful memes are just short-lived ones. But there is more: if memes indeed conform to some characteristics of parasitic species - that is, incidentally more than fifty percent of all extant species according to conservative estimates (Price 1980: 8) - they may share their general property of "evolving slowly" and representing "dead ends in any phylogeny (Price 1980: 11). Although Price qualifies this view, he quotes other parasitologists who thus express current theoretical views: "parasites as a whole are worthy examples of the inexorable march of evolution into blind alleys" (Noble and Noble 1976: 525). Therefore, memes would die, that is cease to replicate, not only selectively because of an intrinsic structural fragility but generally, as a result of a proclivity attached to their specific mode of survival as parasites, not necessarily because of their host's death.

But this is not all. Within a given segment of evolution memes are bound to compete with each other for brain territories and resources which are essential to their existence and reproduction. It can be hypothesized that strains of memes have no choice but to strive to eliminate each other directly through structural disintegration or assimilation - that is by neutralizing the information value of their competitors, or indirectly by instructing their own host to destroy the hosts of other

competing memes. Admittedly, such a formulation make memes' warfare sound and look like a video game, but let us point out that the analogy might not be as far-fetched as it seems, given the fact that on the one hand confrontational video games explicitly mimic human affairs and that on the other hand they are based upon the mutual manipulation of information patterns or sets of instruction, and organisms through the medium of a tool which itself would easily qualify as a meme. The hierarchical depth of parasitism commonly involves several levels of embeddings, and there is no reason why this feature could not be heuristically extended to memes.

The above speculative exploration of the memes as parasites hypothesis can generate falsifiable hypotheses. For instance, Cavalli-Sforza (1971) Cavalli-Sforza and Feldman (1981) have shown how quantitative approaches to the study of sociocultural evolution can be modeled with reference to biological evolution. Nevertheless, the meme hypothesis remains a distant albeit fascinating frontier.

On the one hand, it fits to some degree a long standing intuitive knowledge; countless observations have indeed led to a tradition of human anxiety regarding the power of ideas and the alienating effects of ideologies, the taking over of human behavior by directly or indirectly self-destructive programs; "habits" have been scrutinized with some puzzlement by philosophers and psychologists and have even been characterized as "a second nature," a metaphor which would become literal if the meme hypothesis were substantiated; but, on the other hand, it is deeply counter-intuitive and extremely difficult to operationalize; the conditions which would be required to test this hypothesis are still far from being afforded by current knowledge and means of investigation. Computer viruses and parasitic models at best offer intriguing analogies. Like the "sign" of semiotics, the "meme" of evolutionary biology, or memetic, is a hypothetical entity. However, further advances in the exploration of the meme hypothesis are obviously dependent upon advances in the understanding of the brain because it is generally recognized in evolutionary biology that it is impossible to understand an organism independently from an understanding of the environment within which it has evolved as a part of this environment. Let it suffice, for the time being, to ponder the basic concepts of parasites' evolutionary biology as expressed by Price (1980: 16-24) but by heuristically replacing "parasites" by "memes:" memes are adapted to exploit small, discontinuous environments; memes represent the extreme in specialized resource exploitation; and memes exist in non-equilibrium conditions.

This may provide the shifting of perspective which is necessary to reformulate the fundamental questions of semiotics in a novel, more productive manner, not necessarily by equating signs and memes, but by considering the possibility that memes might be parasite signs and, as such, an important dimension of evolutionary semiosis.

WHY DO MEMES DIE?

By

Paul Bouissac

paul.bouissac@utoronto.ca

University of Toronto

"We have come to the edge of a world of which we have no experience, and where all our pre-conceptions must be recast." --- D'Arcy W. Thompson (1942:77)

Introduction: What is a Meme?

It is being increasingly recognized that the notion of "meme" (Dawkins 1976) as a self-replicating information pattern (cultural unit) whose biotic environment is formed by human, and possibly primate[1], brains is one of the most intriguing, even upsetting hypotheses put forward in recent years. Like the more palatable -- because of its inherent functionalism -- notion of "culturgens" proposed by Lumsden and Wilson (1981), this new way of framing semiosis and cultural dynamism in an evolutionary, Darwinian, perspective should be of prime interest to semioticians in as much as it provides a novel approach to the conceptualization of signs and their action. In spite of some efforts to trace the idea back to earlier metaphoric attempts "to define a cultural analogue of the gene" (Costall 1991: 323) or to show that traditional Western philosophy has always tried to account for the dynamism of signs or ideas (Moritz 1990: 5-9), Dawkins' tentative proposal that cultural units of replication may have some features in common with genes has struck many as an entirely novel, counterintuitive perspective deserving serious consideration, mainly in view of the theoretical context provided by *The Selfish Gene* (Dawkins 1976). Delius (1989), Dennett (1990), Hull (1988), Koch (1986), Moritz (1990), for instance, have devoted considerable efforts to showing how this hypothesis may be much more than a metaphor and may indeed bring about a revolution in the way we conceptualize the dynamics of cultural, mental and intellectual life. This seems all the more interesting since the theoretical link between this hypothesis and earlier, seminal definitions of semiotics can be made without conceptual strain, albeit somewhat unexpectedly: on the one hand, the meme hypothesis matches some important aspects of Peirce's accounts of semiosis and gives a surprising turn to his "perfusion of signs" metaphor; on the other hand, Saussure's definition of semiology as the study of the life of signs in social life (my emphasis) takes up a new meaning if "life" is understood literally, i.e., in its full biological sense, rather than metaphorically as some kind of abstract dynamism.

Let us recall the initial, somewhat awkward formulation of the meme hypothesis: "Just as genes propagate themselves in the gene pool by leaping from body to body via sperms or eggs, so memes propagate themselves in the meme pool by leaping from brain to brain via a process which, in the broad sense can be called imitation. If a scientist hears, or reads about, a good idea, he passes it on to his colleagues and students" (Dawkins 1976: 206). The term "meme" was somewhat playfully coined after the French "même" for "same" and with phonetic allusions both to "mimetic" or "memory" and to "gene." In the paragraph following this introduction of the new concept, Dawkins quoted the summary that one of his colleagues, N.K. Humphrey,

produced in reaction to the reading of an earlier draft of this chapter: memes should be regarded as living structures, not just metaphorically but technically. When you plant a fertile meme in my mind you literally parasitize my brain, turning it into a vehicle for the meme's propagation in just the way a virus may parasitize the genetic mechanism of a host cell. And this isn't just a way of talking -- the meme for, say, "belief in life after death" is actually realized physically, millions of times over, as a structure of the nervous systems of individual men the world over (as quoted in Dawkins 1976: 207).

In his subsequent publications Dawkins returns to the concept of "meme" (1982: 97-117, 1986: 158, 1989: 322) and indicates attempts made by others to develop his hypothesis (e.g., Delius 1990).

Until now, the idea of entities endowed with both genotypic and phenotypic structures evolving in a parasitic relation to the organism whose brains provide them with a vital environment, remains an intriguing and fascinating metaphor which shatters our worldview as if it were an aftershock of Darwinism but it may seem to be too "odd" to be taken at face value. Dawkins himself has been cautious in his subsequent and brief treatments of the "meme" idea, as if he were daunted by the full implications of this emergent theory. However, in the context of the changing epistemological landscape of the 1990s, this reconceptualization is being given new dimensions by a range of recently developed concepts such as computer viruses (e.g., Cohen 1990; Delius 1990) and artificial life (Langton 1992) which provide a quasi-operational context for the speculative manipulation of this new idea (Bouissac 1992). For example, advances in the understanding of self-replication as an emergent property arising from local interactions in fairly simple systems (Reggia et al. 1993) suggest a possible avenue for a formal, canonic description of memes.

However, strong resistance to this approach, ranging from amused disbelief to philosophical arguments -- mostly drawing from the long standing controversy concerning intentionality (e.g., Costall 1991) -- has transformed a seemingly playful suggestion with which eccentric minds would toy into a potentially dangerous frontier of science, as if the Darwinian theory of evolution were bracing for a renewed confrontation with the last defense line of a long established worldview order dominated by dualism (Bouissac 1991).

This paper proposes to explore further the "meme" hypothesis by raising two heuristic questions: "Why and how do memes die?" and "What can we learn from the way they die about the way they live?" Thus, it will focus on some of the features and processes which may account for the successful replication (conservation) or the extinction (dissipation) of "memes," a phenomenon which requires to be examined from a multi-disciplinary perspective. Along the line of Dawkins, "memes" will be taken here as informational structures, or sets of instructions, endowed with their own dynamism (autopoiesis) and constrained by the same evolutionary laws as genes, but their biological status will be more specifically ascribed to parasitism both in the predatory sense -- as N.K. Humphrey first visualized the idea (see quotation above) -- and the symbiotic sense, along the line of the developing paradigm of symbiogenesis (Khakhina 1992).

But a note of caution is in order. In dealing with such problems, it is obvious that the heuristic status of the meme-as-parasite hypothesis should be emphasized even if some scientifically

established data and currently accepted theories are brought into the argument. All too often, the humanities and the social sciences have borrowed ideas out of context from the natural and empirical sciences and have generalized them abusively in the form of all-purpose metaphors of little descriptive value, such as the notion of social Darwinism or the right/left dichotomization of cerebral functions. This contribution to the exploration of the meme hypothesis tries to avoid such pitfalls by a constant concern for the falsifiability of the propositions it may come to formulate. At the very least the relevance to semiotics and to the social sciences of the issues potentially addressed by the meme hypothesis must be acknowledged, and even if the conceptual exploration developed in this paper proves to be misguided it might help better define the limits and pertinence of this challenge to established wisdom.

Memes' Ways of Dying

It can be hypothesized that there are at least four causes which can bring about the demise of a meme. These causes should be critically examined in relation to case studies such as the extinction of a language, the discarding of a fashion, the refutation of a theory (in the range of macro-memes), and the phasing out of a word, a habit, a belief (in the range of micro-memes). However, as a first step in this direction, these causes will be considered here in a purely speculative manner. The first cause is a direct result of the parasitic mode of survival of memes; the other three are not specific to memes but apply to memes as to any other organism submitted to the laws of evolution by selection, although they can be expressed in a meme-specific manner. These various models of extinction will now be examined serially.

In as much as memes depend on other organisms for sustenance and reproduction (replication), their survival is bounded by the life-cycle and reproductive success of their hosts. As bearers of brains which afford the conditions necessary for memes to spread through replication, *Homo sapiens* is a vital resource which is itself dependent upon predation and other environmental commodities for the species' evolution and maintenance. Moreover, *Homo sapiens*' biological mode of survival involves a high degree of motility and dispersal. Therefore, memes can become extinct for the same reasons as parasites. An examination of the life conditions of parasites thus sheds some heuristic light on memes' modalities of existence.

Typically, parasites are dependent upon patchy and ephemeral resources because the other organisms -- plants or animals -- which are their hosts are themselves scattered over large areas and are not constant over time. The feeding specialization of the hosts compounds with the feeding specialization of the parasites, which is often extremely narrow [2]. In addition, a parasite's life-cycle often requires more than one host, thus increasing the complexity of its reproduction, mainly if stages in the parasite's development must match stages in the hosts' lives. Since many parasites themselves use other parasites as hosts, it should be obvious that trophic and reproductive constraints make parasites' survival more complex than is the case for free-living predatory organisms, which depend on a much larger array of feeding resources and whose reproductive process is more flexible. As a result, parasitic species can never reach a state of equilibrium with their environment (i.e., their hosts) unless their parasitic mode of life evolves toward mutualism or even symbiosis. Another remarkable result of the parasitic mode of life is that ecological and genetic factors constantly interact to form within a given species "a patchwork quilt of genetic incompatibilities between closely adjacent populations" (Harper 1977:

412). Low probability of colonization and high probability of extinction in patches are among the consequences of the above properties of parasitic species (Price 1980: 77). In response to such ecological constraints these species have evolved a variety of reproductive strategies such as an extreme longevity, including in some cases extended resting stages -- up to several decades -- which can combine with various sexual and non-sexual modes of reproduction such as mating before dispersal (colonization), self-compatible hermaphroditism or parthenogenesis.

There are obvious homologies between some of these strategies and what can be observed in the case of memes, namely the clonal mode of reproduction and the reliance on extended resting stages in the form of inscriptions -- using a variety of semiotic systems -- stored into non-organismic supports. These periods of latency, which enable memes to bridge the gaps occurring in their vital resources, do not constitute however an absolute warranty of survival since, as in the case of parasites, they depend upon coming across an appropriate host at least within the period of time during which the physical support ensures their conservation.

Another important factor to be considered is that memes cannot be confused with evolved wired-in adaptive behavior. As any parasitic organisms, their biological dynamic exclusively concerns their own replication -- in this respect they are strictly "selfish" to use the metaphor that Dawkins applied to genes -- and consequently are neither detrimental nor beneficial to their hosts by necessity. However, some may afford an adaptive advantage which improve the reproductive success of Homo sapiens genes.[3] The reverse can naturally occur and some memes can become extinct because their own success of replication causes the extinction of their hosts. It must be remembered here that their hosts form a patchy and ephemeral resource and that resting stages are not immune to total destruction (viz. the burning of ancient libraries).

If memes are indeed a crucial factor in the emergence and evolution of cultures, the latter's patterns of patchy development and eventual sudden or slow extinction are compatible with an important consequence of the parasitic mode of life: namely the impossibility of reaching a state of population equilibrium (Price 1980: 44-52).

Beside the death of the host -- or the extinction of its species -- caused either by the ill-adaptive effects of a meme or a combination of memes, or by other factors, memes can die for reasons other than those relating to their parasitic mode of survival. At least three such causes can be considered: changes in the environment, intrinsic fragility, and elimination by other strains of memes. These are general evolutionary conditions applying to all forms of life -- let it be organic or not (Langton 1991).

As any organism, memes cannot be conceptualized independently of their environment. Adaptation by selection upon both genetic and memetic variations operates with respect to environmental factors. Catastrophic changes in memes' environment that is the brain or a particular anatomical, physiological or chemical component of it, may eradicate a meme population or trap it in a dead-end without possibilities of further replications. Local disruptions causing amnesia, general degenerative pathologies, such as Alzheimer's disease, chemical imbalance occurring naturally or being induced by external factors may seal the fate of memes. Since memes have the peculiarity of replicating via modifications of their hosts' behavior, those which are replicated through verbal means are jeopardized by aphasic conditions, those which

spread through observational learning can be threatened by various forms of motor impairments. Such deleterious modifications of the neurological milieu are, from the point of view of memes' evolution, essentially similar to the environmental constraints on any living organism which can become extinct when confronted to sudden and drastic changes.

Another factor which must be taken into consideration when assessing the conditions of survival of memes is their intrinsic structure and degree of complexity and specialization. Complexity entails fragility not only because of a closer dependency on environmental conditions but also because of a higher risk of replication errors. These two factors may compound to drive memes to extinction. An ad-hoc example of the latter could be some secret formulas of ancient medicine or medieval alchemy. Selective secrecy and exclusively oral replication -- i.e., absence of resting stage -- can be intrinsic components of a meme's set of instructions and thus account for its built-in fragility. It can be hypothesized that some memes do not survive beyond a small number of replicative generations. The argument of Dawkins according to which longevity is a criterial feature of memes seems to be hardly defensible. With respect to evolutionary time, how can longevity be measured? Even a pattern of information which would replicate only once would qualify as a meme because of this very property which has been thus demonstrated. A meme is no more necessarily a successful meme than a gene is. Unsuccessful memes are just short-lived ones. But there is more: if memes indeed conform to some characteristics of parasitic species -- that is, incidentally more than fifty percent of all extant species according to conservative estimates (Price 1980: 8) -- they may share their general property of "evolving slowly" and representing "dead ends in any phylogeny (Price 1980: 11). Although Price qualifies this view, he quotes other parasitologists who thus express current theoretical views: "parasites as a whole are worthy examples of the inexorable march of evolution into blind alleys" (Noble and Noble 1976: 525). Therefore, memes would die, that is cease to replicate, not only selectively because of an intrinsic structural fragility but generally, as a result of a proclivity attached to their specific mode of survival as parasites, not necessarily because of their host's death.

But this is not all. Within a given segment of evolution memes are bound to compete with each other for brain territories and resources which are essential to their existence and reproduction. It can be hypothesized that strains of memes have no choice but strive to eliminate each other directly through structural disintegration or assimilation -- that is by neutralizing the information value of their competitors -- or indirectly by instructing their own host to destroy the hosts of other competing memes. Admittedly, such a formulation make memes' warfare sound and look like a video game, but let us point out that the analogy might not be as far-fetched as it seems given the fact that on the one hand confrontational video games explicitly mimic human affairs and that on the other hand they are based upon the mutual manipulation of information patterns or sets of instruction, and organisms through the medium of a tool which itself would easily qualify as a meme. The hierarchical depth of parasitism commonly involves several levels of embeddings, and there is no reason why this feature could not be heuristically extended to memes.

Conclusion: A Program for Evolutionary Semiosis

The above speculative exploration of the memes as parasites hypothesis can generate falsifiable hypotheses. For instance, Cavalli-Sforza (1971), Cavalli-Sforza and Feldman (1981) have shown

how quantitative approaches to the study of socio-cultural evolution can be modeled with reference to biological evolution. Nevertheless, the meme hypothesis remains a distant, albeit fascinating frontier. On the one hand, it fits to some degree a long standing intuitive knowledge; countless observations have indeed led to a tradition of human anxiety regarding the power of ideas and the alienating effects of ideologies, the taking over of human behavior by directly or indirectly self-destructive programs; "habits" have been scrutinized with some puzzlement by philosophers and psychologists and have even been characterized as "a second nature," a metaphor which would become literal if the meme hypothesis were substantiated; but, on the other hand, it is deeply counter-intuitive and extremely difficult to operationalize; the conditions which would be required to test this hypothesis are still far from being afforded by current knowledge and means of investigation. Computer viruses and parasitic models, at best, offer intriguing analogies. Like the "sign" of semiotics, the "meme" of evolutionary biology or memetic is a hypothetical entity. It raises many questions and solves none. It is however the contention of this paper that it improves the quality of the questions raised through delineating what could be called a field of relevance and through shifting, on the epistemological spectrum, the heuristic speculation further toward theoretical and empirical determination of cultural evolution. Further advances in the exploration of the meme hypothesis are obviously depending upon advances in the understanding of the brain because it is generally recognized in evolutionary biology that it is impossible to understand an organism independently from an understanding of the environment within which it has evolved as a part of this environment. Let it suffice for the time being to ponder the basic concepts of parasites' evolutionary biology as expressed by Price (1980: 16-24) but by heuristically replacing "parasites" by "memes:" memes are adapted to exploit small, discontinuous environments; memes represent the extreme in specialized resource exploitation; and memes exist in non-equilibrium conditions. This may provide the shifting of perspective which is necessary to reformulate the fundamental questions of semiotics in a novel, more productive manner, not necessarily by equating signs and memes, but by considering the possibility that memes might be parasite's signs, and, as such, an important dimension of evolutionary semiosis.

Notes

[1]. However, Bonner who defined memes as "any bit or any collection of bits of information passed by behavioral means from one individual to another" (1980), extends the operationality of this concept to social animals well beyond the primates (1990: 28-31).

[2]. It must also be kept in mind that parasites influence many aspects of their hosts' qualities, thus altering the hosts' ecological system. "Behavior, reproductive potential, competitive ability, and susceptibility to predation may all be modified and the degrees of change will differ with levels of infection. This variability in the host population, superimposed on the genotypic and phenotypic differences within it, greatly complicates its ecological and evolutionary processes" (Price 1980: 10-11).

[3]. In the same way as random genetic variations sometimes turn out to be adaptive, thus causing evolution to occur, memes can both be aleatoric and occasionally generate in their hosts behavioral modifications which are adaptive (Bouissac 1992). However, meme-driven cultural habits may be only relatively adaptive with respect to a temporary subset of conditions, and may happen to be devastating in the long run. Historical time must be always measured against evolutionary time when assessing cultural changes.

THE HUMAN AGENCY OF MEME MACHINES

An extended review of:

Blackmore, Susan (1999) *The Meme Machine*.

Oxford: Oxford Univ. Press. 264 pp. ISBN 0 19 850 365 2

By

Gary Boyd

Concordia University

1 Importance

For any thoughtful reader, Susan Blackmore's *Meme Machine* is an important book because it clearly explains and illustrates the basic import of the new field of memetics. Actually memetics did not just spring from the head of Zeus (Dawkins) fully formed, but like Barkow, Cosmides and Tooby's (1998) evolutionary psychology, rather it is part of a general contemporary movement to extend evolutionary explanation beyond the purely biological world. At best, memetic evolutionary explanation will become nearly as central to the social sciences as Darwinian evolution has been to the biological sciences. At worst, memetics might conceivably become another way to deny the uniqueness of each mysterious human being. Or as Jacoby (1975) would caution, memetics qua ideology like the computer-metaphor for mind, could become yet another example of "*social amnesia*"- of reification leading to further alienation. Having acknowledged that possibility I must go on to state that current work makes me rather confident that memetics insights will actually help us find many new solutions to educational and political problems.

"*How is memetic evolution steerable?*" that is the key question and the one which Blackmore's *Meme Machine* poses and partly answers with good heuristics which should lead to real progress.

2 Three Key Achievements:

2.1 Educating engagingly:

The first of Susan Blackmore's main achievements in this volume is to provide a pleasantly, even intriguingly, readable understandable respectable book which one can offer to friends and students who ask: "*What is all this meme or memetics excitement about?*"

Susan Blackmore has written a thoroughly enjoyable and informative book for all reasonably well educated people such as readers of the *New Scientist*, or the *Scientific American* and *Harper's* magazines. Her style is fluent, clear, coherent, convincing, and entertaining. The *Meme Machine* is itself a carrier of an infectious and contagious 'memplex' carefully crafted to become a symbiocytic fellow-traveler for us altruists who are teachers of the various sciences.

2.2 Advancing Science:

As Dr. Blackmore the scientist describes science (p. 202) "*Science like religion is a mass of memplexes ... Science is fundamentally a process; a set of methods for trying to distinguish true memes from false ones. At its heart lies the idea of building theories about the world and testing them, rather like perceptual systems do*". She points out that "*Evolutionary theory faced enormous opposition because it provided a view of humans that many humans do not like. The same will probably be true for memetics. However at the heart of science lies the method of demanding tests of any idea. Scientists must predict what will happen if a particular theory is valid, and then find out if it is so. That is what I have tried to do with the theory of memetics.*"

The prediction of probable ubiquity of memetic theory among social scientists can be tested by trying out the explanatory framework on various 'hard' case phenomena in the various social sciences. This is what Blackmore begins to do in a schematic qualitative way. Her analytic forays are well grounded in the literature, and self-critical enough to be plausible. They are also exciting enough, and controversial enough to inspire much further thought, and to warrant much further work. That I believe is her main scientific achievement here.

Social science theories such as memetics and e.g. 19th century social-Darwinism can however be either self-fulfilling or self-defeating prophecies. As they gain currency they become ever more true; or contrariwise as in the case of social Darwinism as it gained currency it evoked a wave of objections which constructed it to be false.

Memetics is first of all an explanatory theory with great heuristic value. I am confident, partly from reading Blackmore as well as Dawkins, Dennett, and many of the others, that it will indeed lead-on self-fulfillingly to important new truthful explanatory sub-theories and also even to, at least fuzzily, quantitative predictive models of cultural propagation, and evolution.

2.3 Liberating memplexes:

Blackmore's third main achievement (- very much in line with her previous works - e.g. Blackmore, 1996) is to make challenges which liberate us from habitual and wishful thinking, and oppressive ideology. For example, consider this statement of hers on p. 241-2: "*But this is still a cop out*". As Daniel Dennett (1984) says '*The "independent" mind struggling to protect itself from dangerous memes is a myth*'. So we must ask: who gets to choose? If we take memetics seriously then the 'me' that could do the choosing is itself a memetic construct: a fluid and ever-changing group of memes installed in a complicated meme machine. The choices made will be a product of my genetic and memetic history in a given environment, not of some separate self that can 'have' a life purpose and overrule the memes that make it up. This is the power and beauty of memetics: it allows us to see how human lives language and creativity all come about through the same kind of replicator power as did design in the biological world.

What she does raise explicitly is the question of free-will and human agency pointing out that (p. 237) "*...the self that is supposed to have free will is just a story that forms part of a vast memplex, and a false story at that. On this view all human actions whether conscious or not, come from complex interactions between memes genes and all their products, in complicated*

environments. The self is not the initiator of actions, it does not have consciousness, and it does not 'do' the deliberating. There is no truth in the idea of an inner self inside my body that controls the body and is conscious. Since this is false so is the idea of my conscious self having free will."

This is arguably the most controversial claim in Blackmore's book. It is well warranted by the rest of the book. Yet it sits oddly in the lifework of a very responsible creative and apparently self-determined author who in her previous work has been circumspectly devoted to the critical scientific exploration and as it turned out refutation of most of the ubiquitous claims of parapsychology, and of the paranormal (Blackmore, 1996).

Right now I feel I can and must choose between going on with this review or going for a walk amid the beauty of the falling maple leaves. Without these in a sense illusory options I would feel my life to be pointless. The conflict between the option to go on writing versus the option of a Sunday stroll is a conscious epiphenomenon of contending memplexes embodied in the neuronal groups of my CNS (Central Nervous System), and triggered or reinforced by various current perceptions. The human-being which chooses encompasses all this and moreover has historical depth in my and others' socialization and geographical and biochemical history. It seems we memplex nexii must tell our stories anew if we wish to go on elaborating and propagating critical realist science.

Is this possible? Yes, theoretically it is if the *memetic* science memplex proves to be contagious enough and co-travels with the Critical Realist Science memplex. This can happen but not without the pruning and re-organizing or killing off (and grieving?) many religious memplexes which have evolved to behave to prevent pruning and re-organization let alone replacement.

In my view the memetic explanatory mechanism does not rule out purposive intention or at least Dennett's 'intentional stance', but it does require a different account of it -one which has not yet been scientifically articulated. Dennett went some way along toward a better account, but without making links to memetics, in his (1984) book on the varieties of free will worth wanting. Probably the best currently accessible treatments of consciousness are those of the neurophysiologists D'Amasio (1999) e.g.- p.313. "*...the plotting of a relationship between any object and the organism becomes the feeling of a feeling. The mysterious first-person perspective of consciousness consists of newly-minted knowledge expressed as feeling ...Creativity - the ability to generate new ideas and artifacts requires more than consciousness can ever provide. It requires abundant memory, fine reasoning ability, language. But consciousness' revelations guide the process.*" (Tonini and Edelman, 2000). My reading of both is that they are fully compatible with meme-complex acquisition (in the form of synapse weightings and neuronal group selections), and neuronal memplex execution processes which generate both plans and the emotions that evoke feelings which along with other physiological homeostatic regulators, produce our decisions.

According to this theory, whether you will actually allow yourself to accept the tempting memplexes which Susan offers, and so to see all the human world in the memetic realist way, or not, is up to the ways memplexes are executing in your body, which together are you!

3 Four Adumbrative Criticisms:

3.1 Memes as replicands or replicators?

Like others Susan Blackmore sidesteps the task of defining memes any more precisely than Dawkins did. Are memes *replicands* or *replicators*? - i.e. are they *merely catalysts* for their own reproduction via the host's pre-existing reproductive mechanisms like viruses, or do they become *embedded as self-reproducers* in the host human animal (- like bacterial parasites)?

As others have pointed out precise definition poses a serious challenge which must be taken up. My own offering as a possibly better (?) definition is: that a meme is a bounded set of modulations on any carrier which when received by an animal has by virtue of its configuration (Shannon information of an aesthetic, &/or pseudo sustenential, &/or proto-propagative propitious character which is attractive to that animal's pre-embodied memplexes) an high probability of being transduced into neuronal group and synapse threshold representations which result in effectively identical replications of the meme as outputted modulations on other carriers (which of course tend to produce further propagation (- seduction, infection and contagion) via other animals. This definition depends on the engineering definitions: of carriers and modulations, transducers, receivers, Shannon-information and transformation which in all fairness, may not be commonplaces for Blackmore nor for others writing memetics. It also assumes something like Gerald Edelman's (1992) extended Theory of Neuronal Group Selection (neuronal group Darwinism) as one basis for transduction of received input into active neurophysiological quasi-self-organizing, transformative and reproductive humanimal (i.e. human physiological) processes.

3.2 Not just Three Essentials for Darwinian Evolution but Six

This extension certainly does not seriously invalidate Blackmore's arguments, but her arguments are rendered somewhat imprecise by the neglect of the additional three factors necessary for Darwinian evolution. It is stated p.10 that "*Darwin's argument requires three main features: variation, selection and retention (or heredity).*" This is true and necessary but according to Williams (1994) and others, *not sufficient*. For neo-Darwinian evolution, as now understood, six features are necessary. They all it seems to me, should also be quite important to think about for understanding meme and memplex evolution:

It must depend on a **population** of **patterns** of some type (they can be patterns of activity, not just of objects).

Copies are made of these patterns (the smallest reliably copied pattern defines the basic unit of replication - e.g. a meme).

Variation - The pattern-units must occasionally **vary** (due to mutation copying errors, or reshuffling of parts).

Competition - Variant patterns must **compete** to occupy some **limited space** (e.g. someone's CNS).

Selection - The *relative* reproductive success of variants must be influenced by the environment (which also usually co-evolves with the organisms - e.g. Dawkins' Extended Phenotype theory).

Heredity -The *makeup* of the *next generation* of the population must depend on which variants survive to be copied.

It is worth noting that the main environment for most memes is constituted by other memes and especially by memeplexes (& "selfplexes") (- just as the main environment for any gene are other neighboring genes). Bhaktin's question: "*Who is doing the talking?*" (Wertsch, 1991) is also relevant for specifying the selective environment of a meme or memeplex.

3.3 Not just One Emergent Memetic level but about six memeplex levels

All memes are not created equal, and especially all memeplexes are not created equal. I have argued (Boyd, 1997) that at least six different levels of memeplexes have emerged historically in co-evolution with populations of informationally coupled humanimals (Homo sapiens) and their/our environments:

The *simple viral* aesthetically attractive, pseudo sustenential (or actually sustenential/symbiotic) memes, { e.g. Happy-faces :-), apples, paper-money}. above these emerged *negotiative* ethically and morally attractive memeplexes, {e.g. "do-as-you-would-be-done-by"} above those what I refer to as *conjugative-integrative identi-memeplexes* these are what Blackmore has named "*selfplexes*"- which compose our ordinary personal identities. Emerging above the selfplexes that we are addicted to, is another level of those memeplexes which can free us from addictions - "*liberative*" memeplexes. {e.g., ignore this sentence!}

Then emerging evolutionarily from those are the "*scientosophic*" (i.e. scientific and philosophic- or universal science) memeplexes (- including those of Blackmore's book itself) which can liberate us from superstitious memeplexes, and give us good heuristics and/or generative predictive models and above those emerge what I am now inclined to call: "*existential*" hope-despair imbuing and sustaining, (at best perhaps "*symvivial*" = harmonious-Life-unity-hope survival-promoting) memeplexes.

3.4 The trouble with one "selfplex" per customer

The trouble with "selfplex" is that it probably lumps together a number of identity component memeplex entities all hosted by humanimal bodies. For most people the self may usually feel singular and integrated, but it is very apparent to others that we often actually exhibit at least several different personae (e.g. Rowan, 1990). The extreme cases are those of Multiple Personality Syndrome on the one hand and the wonderful self-integration of some great figures or saints on the other. For the rest of us we serve as stages on which various personae or identi-memeplexes take their turns at performing and contending with one-another. We each are a little cast of selfplex actors, if you like.

4 The Meme Machine from a Critical Realist Stance

Is Blackmore's unstated philosophical stance possibly Critical Realism?

The presuppositions of a scientific essay are almost always as important as what is explicitly stated. It is a little difficult to determine the philosophy of science which Blackmore espouses. It is clearly not naive realism, nor superficial observational empiricism, nor positivist operationalism. The actual methodology used is unstated. It might very possibly be either Methodological Pragmatism (Rescher, 1997), constructivism (Von Glaserfeld, 1987), or more hopefully Critical Realism (Bhaskar, 1989).

Memetics, this new causal historical explanatory theory which can be used to generate models of particular source systems, is expounded by Blackmore in a particular qualitative way which might fit all three philosophies of science. Some of the scientific commonsense pre-suppositions of Memetic theory, and some of the vested interests which memeplex evolution models (e.g. of a religion) might harm or benefit are clearly indicated - which taken together might allow categorizing her work as a creative foray in Critical Realism. Adding more critical emphasis on identifying the kinds of memeplexes which are the reproductive forms of domination that Marx identified and named 'reification' and 'alienation' would nicely put the work in the mainstream of Critical Realism today.

If we start from a 'Critical Realist' philosophical position, i.e. An ontology of the real world as structured differentiated and ever changing, and an understanding of scientific activity as the continual process of the empirically controlled retrodiction of explanatory structures from the manifest phenomena which are produced by them, then Blackmore in the *Meme Machine* is doing science. The possibly real explanatory structures are humanimally embodied 'memeplexes' and in particular 'selfplexes' which are proposed to account for a large part of the phenomena of human behavior. They sustain questioning, and thus are partly validated by her explorations of accepted knowledge.

The *Meme Machine* also participates in the critical emancipative transformative agenda of Critical Realism. Emancipative critique according to Bhaskar (1989) consists in asking to what extent are enduring structures being merely reproduced in novel forms, and to what extent are they being transformed to replace un-needed, unwanted and oppressive sources of determination by wanted and empowering ones. Memeplex reproduction and propagation is certainly often unwanted and oppressive, but is it also the basis of human agency and indeed the human spirit? Blackmore seems to contend effectively that it is such. What emerges is a rather odd kind of human agency - the agency of millions of complexly interacting memes embodied in various humanimal nervous systems and artifacts.

This poses a problem for Critical Realists with an emancipative concern such as Bhaskar, because if memetic processes are the 'real' underlying generative processes of culture and identity, then the most important needs of human beings as such arise from our biologically evolved imperatives to reproduce and propagate often totally incompatible competitive memeplexes. Does not emancipation now mean that everyone needs to be liberated from those parts of their own "selfplexes" which cannot propagate symbiotically with those of others and

with our biophysical niches? This selfplex competition survival question is not explicitly raised by Blackmore, but it is I think implicit in her exposition.

5. Conclusion

All definitions of 'human nature' have been, and are, very political in the sense that their deployment advantages some sorts (classes?) of people at the expense of others. As Berry, (1986) concludes: "*Any theory (of human nature) itself is part of the problem and constitutive of the issue.*" Who then benefits, and who malefits, from the memetic definition of human nature being purveyed by Susan Blackmore? Critical Realist social scientists will benefit. Socio-cultural engineers will benefit. educators will benefit. POST-post-modernist engaged atheist intellectual selfplexes are bound to benefit. On the other hand various sorts of 'True-believers', including possibly even 'true believers' in Memetics, will suffer as this work, with its liberative anti-magical reframing effects, climbs up the best-seller list (and I think it should).

INTRODUCTION TO THE CRISIS OF THE MIND

By
Richard Brodie

What a waste it is to lose one's mind, or not to have a mind is very wasteful.

—Dan Quayle, (Mutating the memes in the United Negro College Fund's motto, "A mind is a terrible thing to waste.")

There *is* some good news in this book. So before I get into how mind viruses are spreading wildly throughout the world—infesting people with unwanted programming like the Michelangelo computer virus infects computers with self-destruct instructions—I'll start with the good news.

The good news is that the long-awaited scientific theory unifying biology, psychology, and cognitive science is here. An interdisciplinary effort by scientists in all those fields over the last 20 years or so—really back to 1859 and Charles Darwin, if you like—has produced a new science called *memetics*.

The science of memetics is based on evolution. Darwin's theory of the evolution of species by natural selection utterly transformed the field of biology. Scientists are now applying modern evolutionary theory to the way the mind works, the way people learn and grow, the way culture progresses. In so doing, the field of psychology will ultimately be as transformed by the scientists researching memetics as biology was by Darwin.

For those of us who yearn to understand ourselves, learning about memetics gives us a huge amount of satisfaction. I also believe that people who understand memetics will have an increasing advantage in life, especially in preventing themselves from being manipulated or taken advantage of. If you better understand how your mind works, you can better navigate through a world of increasingly subtle manipulation.

Now the bad news. The bad news is that this book raises more questions than it answers. In particular, memetics has uncovered the existence of *viruses of the mind*, but gives us few insights into what to do about them.

Viruses of the mind have been with us throughout history, but are constantly evolving and changing. They are infectious pieces of our culture that spread rapidly throughout a population, altering people's thoughts and lives in their wake. They include everything from relatively harmless mind viruses, such as miniskirts and slang phrases, to mind viruses that seriously derail people's lives, such as the cycle of unwed mothers on welfare, the Crips and Bloods youth gangs and the Branch Davidian religious cult. When these pieces of culture are ones we like, there's no problem. However, as the Michelangelo computer virus programs computers with instructions to destroy their data, viruses of the mind can program us to think and behave in ways that are destructive to our lives.

This is the most surprising and most profound insight from the science of memetics: your thoughts are not always your own original ideas. You catch thoughts—you get infected with them, both directly from other people and indirectly from viruses of the mind. People don't seem to like the idea that they aren't in control of their thoughts. The reluctance of people to even consider this notion is probably the main reason the scientific work done so far is not better known. As we'll see, ideas people don't like have a hard time catching on.

Further compounding the problem, you don't immediately know whether the programming you get from a given mind virus is harmful or beneficial. Nobody every joined a religious cult with the intention of getting brainwashed, moving to Guyana, and committing suicide. When the teenage Bill Gates caught the poker-playing mind virus at Harvard, was that harmful because it kept him from his studies? Or was it beneficial because it helped sway his decision to drop out, start Microsoft, and become a multibillionaire?

Paradigm shift

Every so often, the world of science experiences something called a *paradigm shift*. That happens when one of the basic, underlying assumptions we've been living with changes, such as when we shifted from looking at the universe as revolving around the earth to the earth revolving around the sun. Another shift occurred when Einstein discovered the relationships between space and time and between energy and matter. Each of these paradigm shifts took some time to penetrate the scientific community, and even longer to become accepted by the general public.

Viruses of the mind, and the whole science of memetics, represent a major paradigm shift in the science of the mind.

Because understanding this new science involves a significant change in the way people think about the mind and culture, it has been difficult for people to grasp. As with any paradigm shift, memetics doesn't fit into our existing way of looking at things, of understanding the world.

The trick to learning a new paradigm is to set aside your current one while you're learning rather than attempt to fit the new knowledge into your existing model. It won't fit! If you're willing to set aside your current thinking long enough to consider four concepts, some or all of which may be new to you, you'll be rewarded with an understanding of memetics. With that understanding, I hope, comes a call to action for anyone concerned with the future of human life.

The first concept—the star of the show—is the *meme*, which I introduce in Chapter 1 and which plays a leading role throughout this book. The meme, which rhymes with "beam," is the basic building block of culture in the same way the gene is the basic building block of life. As I outline in Chapter 2, memes are not only the building blocks of culture on a large scale—making up countries, languages, religions—but also on a small scale: memes are the building blocks of your mind, the programming of your mental "computer."

Second is the concept of *virus*. It's well known that viruses exist in biology and in the world of computers. Now we'll see how they show up in the world of mind and culture, the world of

memetics. In Chapter 3, I'll draw parallels between the three different universes that viruses live in to show what we can expect from mind viruses in the future.

The third concept that contributes to this paradigm shift is *evolution*. Evolution is one of those words that many people use, thinking they are talking about the same thing, but really having different ideas of what evolution is and means. I'll discuss scientists' most current theory of evolution in Chapter 4, and how it applies to memes in Chapter 5.

The fourth concept necessary to understanding mind viruses is the new science of *evolutionary psychology*. This field examines the biases and mechanisms of our minds that evolved to support our survival and reproduction. Some of these biases take the form of psychological *buttons* that can be pushed to penetrate our mental defenses. I called this part of the book "Crisis of the Mind" rather than simply "Introduction" because the former pushes more buttons: it attracts more attention and more people will read it. I called this book *Virus of the Mind* rather than *Introduction to Memetics* for the same reason.

Currently a controversial topic, evolutionary psychology explores and explains many of the stereotypical differences between men and women, especially in the realm of mating behavior. Chapter 6 is about the mating part of evolutionary psychology; Chapter 7 covers the survival aspect.

Memetics builds on these four conceptual blocks to form a new paradigm of how culture evolved and is evolving. It illuminates a major decision point for humanity:

Will we allow natural selection to evolve us randomly, without regard for our happiness, satisfaction, or spirit? Or will we seize the reins of our own evolution and pick a direction for ourselves?

Memetics gives us the knowledge and power to direct our own evolution more than at any time in history. Now that we have that power, what will we do with it?

A threat to humanity

A mind virus is not spread by sneezing, like the flu, or by sex, like AIDS. It's not a physical thing. Mind viruses are spread by something as simple as communicating. I discuss the ways we get programmed by mind viruses in Chapter 8. In a way, mind viruses are the price of one of the freedoms most dear to us: freedom of speech. The more freedom there is to put forth any communication, the more welcoming the environment for mind viruses.

Some mind viruses arise spontaneously, as I discuss in Chapters 9 and 10; some are created intentionally, as I cover in Chapter 11. But all of them share one thing in common:

Once created, a virus of the mind gains a life *independent* of its creator and evolves quickly to infect as many people as possible.

Viruses of the mind are not some far-off future worry like the sun burning out or the earth being hit by a comet. They are here with us now—have been with us since before recorded history—and they are evolving to become better and better at their job of infecting us. We are being infected in some new ways—television, popular music, sales techniques—but also in very ancient ways—education, religious teachings, even talking to our closest friends. Our parents unwittingly infected us when we were kids. If you have children, chances are you are spreading the viruses to them every day.

Read a newspaper? Catch a mind virus. Listen to the radio? Catch a mind virus. Hang out with your friends and shoot the breeze about nothing in particular? Catch one mind virus after another. If your life isn't going the way you would like, you can bet mind viruses are playing a large part. Having relationship problems? Mind viruses take over parts of your brain and divert you from what would give you long-term happiness in a relationship. Having trouble in your job or career? Mind viruses cloud your future and steer you along a career path that supports their agenda, not your quality of life.

Cult religions are springing up everywhere, the result of more and more powerful mind viruses. These cults take control of people's minds and make members engage in bizarre behavior ranging from odd rituals to mass suicide. If you think you're immune, remember: nobody ever set out intentionally to join a cult and have their mind taken over. It's the work of tricky and pernicious mind viruses. And once the founder of the cult starts the process, the virus of the mind takes on a life of its own.

Because of mass media and direct elections, the U.S. and other governments are becoming more and more subject to infection by mind viruses. A politician today cannot be elected without coming up with an effective image that pushes people's buttons and gets the votes. "We're having a crisis and only I can fix it," they say, or, "Those other guys have caused all these problems; surely any change is better than what we've got!" Politicians' well-crafted images are hooks into some of the most elaborate and pervasive mind viruses infecting society today.

What brand of soft drink do you buy? The ones that sell the most cost twice as much as unadvertised store brands. The extra money goes into television advertising, sending out the spores of ever more penetrating mind viruses that literally take control of your mind and make you push your shopping cart over to their shelf. Successfully programming your mind to believe that you prefer that brand, advertising agencies are among the most brazen and calculating of the mind virus instigators.

The unchecked spread of mind viruses shows up most alarmingly in the state of our children today. Starting with the inner cities and quickly spreading, the mind viruses infecting many children are pushing them into hopelessness, single motherhood, and gang warfare. Many children seem to be losing their sense of values and taking off in some very unsettling directions. Chapter 12 discusses the possibility of disinfection for us and our children.

My agenda

Let me tell you right now, I have an agenda in writing this book, and that agenda is to make a difference in people's lives. Some of the content in this book *could* be used for self-improvement. You might not expect a book about science to include ideas from the self-development field, but the science of memetics deals with the mind, with people's lives. Understanding memetics can naturally help increase the quality of people's lives. In the first place, I would never have written this book—or my first book, *Getting Past OK*—if I had not intentionally disinfected myself of many of the memes I got as I grew up and reprogrammed myself with new memes. What new memes would you choose to reprogram yourself with, given the chance? That's entirely up to you. I had no idea what that even *meant* when I started this research. Now that I do, I choose to program myself with memes that support my values in life rather than ones that support the agendas of viruses of the mind. You can do that or something different. But you won't have the option to do anything like that unless you understand memetics.

The reason I'm writing this book is that I really *enjoy* making a difference in people's lives. My agenda in writing *Virus of the Mind* is to do just that. I believe that knowledge of memetics is important, and so I'm spreading it. I'm not just writing this book as an intellectual exercise. Although this book is *about* science, it's obviously not a scientific text. It's designed with an intention, and that is to consciously spread the new paradigm of memetics because I think it's important.

Consciously spreading ideas you consider important is one way to combat mind viruses.

Have you ever wondered why life seems so complicated today, more complicated and stressful year after year? One reason is the ever-evolving army of mind viruses, taking a greater and greater share of your mind, diverting you from your pursuit of happiness and due to have an even greater effect on the next generation.

Ever wonder why, with greater and greater progress and technology, life doesn't seem to get simpler, but just the reverse? Every time you're exposed to a new virus of the mind, your mind takes on just a little more stress, a little more confusion.

People are flocking to everything from psychotherapy to the New Age movement to try to relieve the crushing burden of stress. Doctors are more and more certain that excess stress is our No. 1 killer, but experts disagree on what causes stress and how to cure it. The medical community talked of stressed-out "Type A" and laid-back "Type B" personalities, with no clear idea of what caused someone to have one or the other. And even the "Type B's" had stress-related symptoms sometimes. The new science of memetics gives much insight into the problem of stress.

Taking over bits of your mind and pulling you in different directions, mind viruses distract you from what's most important to you in life and cause confusion, stress, and even despair.

They infect your mind, programming you with directions that point you away from where you want to go. Since this all happens unconsciously, all you're aware of is that, as you grow older, life becomes more stressful, less fun, more of a drag, and less meaningful. You may feel your motivation slipping away. You may get less excited about things than you used to. These are some of the effects of infection by a virus of the mind, an infection we cannot avoid entirely short of living in complete isolation from birth.

You *can*, however, begin to disinfect yourself. My hope is that the understanding people gain from this book will be a big first step in that disinfection. But it takes a bit of effort to teach yourself a new paradigm.

Birth of a new paradigm

It's always been hard for scientists to communicate their ideas to the general public. Science, by its very nature, is an artificial selection of ideas based on rigorous testing of their usefulness *rather than on people's gut feelings*. As such, new scientific ideas tend to rub people the wrong way at first and produce predictable reactions. When Charles Darwin first proposed his ideas on natural selection in 1859, there were several stages of public reaction, stages that any revolutionary new scientific idea seems to go through before becoming accepted:

1. Complacency/Marginalization. At first, the new theory is seen as an off-the-wall idea: quaint, but not a serious threat to the dominant world view—perhaps a simple variant of some already known theory. Memetics is graduating from this stage to the next as I write this. Editors of *The New York Times Magazine* of Jan. 22, 1995, picked up on the growing use of the word *meme* and mildly attempted to marginalize it: "A skeptic might wonder what the notion of a meme adds to the paradigm of cultural evolution. Perhaps there's nothing new under the sun." By the end of this book, readers will discover that rather than adding to the existing paradigm of cultural evolution, memetics itself is a new and more powerful paradigm.

2. Ridicule. Complacency fades as the new idea refuses to die, resulting in ridicule by people who clearly and laughingly see that it's inconsistent with something they hold to be true. In Darwin's case, contemporaries laughed at Darwin's inability to see the necessity of a Supreme Designer doing the selecting. Darwin was frustrated by his seeming inability to communicate this new paradigm. Similar ridicule of memetics is seen from time to time in the few places memetics is discussed, such as the alt.memetics newsgroup on the Internet.

3. Criticism. As the new idea gains acceptance, people who have held conflicting world views for some time, or who have their reputation invested in old paradigms, take off their gloves. Darwinism is still being attacked today by creationists who believe it conflicts with their Truth. It's possible that this book will touch off serious criticism of memetics. If it does, we shouldn't worry; it's the nature of a paradigm shift.

4. Acceptance. Finally, enough people make the leap to the new paradigm that it gains psychological as well as intellectual acceptance. Those who understand the new ideas are no longer as alone and unloved as Columbus among the flat-earth believers. The new world agrees

on the new paradigm. Peer pressure starts to work for it rather than against it. It's begun to be taught in elementary schools. Scientists can move on to their next challenge.

Our minds, it seems, are not well equipped to understand how they themselves work. You, in fact, may at first be very confused or distracted, or suddenly get tired as you read this, or even get angry just from reading these words. Although right now you may think this statement absurd, those feelings and symptoms are actually the defense mechanisms of mind viruses. They have evolved to be very protective of the parts of your mind they have stolen, and any attempts to cleanse yourself of them can trigger reactions.

If you experience one or more of these reactions while reading this book, don't worry: the reaction will pass if you ride it out. If you do, you'll be rewarded with a powerful tool for your future and the future of humanity.

THE MEME HUNTER

BY
ANDREW BROWN

A British psychologist prowls for hard evidence that memes -- ideas that reproduce genetically, like viruses -- actually exist. What's one of the prime habitats? The Internet.

Suppose that every thought you have -- including this one -- is an autonomous parasite in your brain: a pattern of brain cells that copies itself from mind to mind.

Congratulations! You've just caught a meme.

A meme, according to Richard Dawkins, who coined the word in his bestseller "The Selfish Gene," is anything a human can remember and transmit. Memes are meant to be the brain's equivalent of DNA. A meme could be an idea or a snatch of music or a dance. So long as it gets copied between brains fairly accurately and competes with other copies for survival, it will do as a candidate for evolution. If memes exist, they have modified the world just as genes have: Genes have made the biosphere; memes have made the memeosphere, the place where human beings exist.

The idea is catchy -- the "meme" meme is particularly popular online -- but controversial. Dawkins himself has withdrawn from it a little. He said last year: "There are people who take memes seriously and there are people who don't. I sort of sit on the fence, and don't mind seriously one way or the other. That wasn't my purpose in producing them."

But lots of smart people do take them seriously. Daniel Dennett, the leading philosopher of artificial intelligence, writes as if the existence of memes were an established fact. A human being, he says, is an animal infested by memes.

And Susan Blackmore, a British psychologist who has been the scourge of every sort of paranormal nonsense for the last 20 years, has got memes bad. She is trying to work out ways to find them in the wild.

"I want to do away with the notion of 'ideas' and look at brain structures and behaviors," she says. "The brain structures may be hard to find. They probably consist of patterns of activation, which will not be there all the time. But I have talked at you for half an hour -- that's a behavior. You have written down some of my words. That's another behavior. And so the memes have been copied. It is a very loose form of copying -- but we can study the process."

Talking to Blackmore is exhausting and invigorating all at once. Ideas fountain out of her like champagne in an intoxicating stream; it hardly matters whether they are bubbles or not.

"If you take a common-sense view," she says, "humans are units called selves which somehow generate ideas from within. But when you take the meme's-eye view, you see brains as hosts for memes. We don't own or generate 'our' ideas. Nor are they working for our purposes. We can imagine meaning in them, but really all that's going on is imitation and storage," she says.

These ideas fit in with Blackmore's Buddhism, where the human personality is no more than a swarm of causes and consequences, temporarily bundled in a body. But they also fit with her sense of a crisis in academic psychology: "I've spent 25 years in psychology and it's an absolute mess. We don't have a decent theory of emotions, or of motivations."

Meme theory seems to offer a way out of this. If beliefs prosper for their own reasons, and not for the good of the organism that contains them, then this would explain the inexhaustible capacity of the human mind to produce bad ideas and disastrous plans. It does not matter to the success of a belief if the original brain that carries it dies, provided it has been spread to more brains in the meantime. In Daniel Dennett's slogan: "A scholar is just a library's way of making another library."

Blackmore says that a good test for the independent existence of memes would look for "behavior that is not in the interest of the person -- but purely in the interest of the propagation of the memes."

The classic example of this spread is religious: "Martyrdom" originally meant "testifying." It's just that handing out tracts or making speeches turned out to be a less effective marketing method than getting chewed by lions in public. "The blood of the martyrs is the seed of the church," as the meme has it.

All this leaves out the consideration of what a meme actually is: how you can identify an individual, transmissible unit of culture. And this is a huge difficulty for meme theory, one that has led most people who have considered the idea to attack it. For everything we know about human culture suggests that it is hugely different from the genetic system.

John Maynard Smith sides with Dawkins against Stephen Jay Gould in battles over biological evolution, but has nonetheless expressed very clearly one of the main theoretical objections to

memes: "Two features are necessary for any genetic system that is to support adaptive evolution. The system should be digital, and it should not support 'the inheritance of adapted characters.'"

Genetic copying is digital -- the DNA strings code for 20 discrete amino acids, and nothing in between -- while cultural copying is analog and fuzzy. Cultural evolution is Lamarckian -- ideas are modified by experience before being passed on -- whereas it is a central dogma of biology that evolution cannot be Lamarckian. Genes are not selected directly, but as a result of their effects; a gene that makes an animal grow or behave in a certain way will be copied (or not) as a result of the behavior or capacities of the animal that carries it. (The animal's physical and behavioral characteristics are known in the jargon as the phenotype; the DNA that encodes the instructions to build the phenotype is the genotype, so that biologists say that genotypes are selected for the phenotypical effects.) But meme candidates are selected directly.

Culture appears to be a ladder -- especially to a scientist like Dawkins -- whereas evolution is a bush. Stephen Jay Gould calls memes "a meaningless metaphor"; virtual-reality pioneer Jaron Lanier thinks they are dangerous nonsense that promotes sloppy habits of thought. Yet it is all too easy for meme believers to dismiss their opponents as people infested with mind viruses -- as if they were not in the same situation themselves.

None of these difficulties bothers Susan Blackmore. She takes her strength from a syllogism: If the Darwinian algorithm is the only way we know to generate order and complexity in nature, which it is; and if our minds are full of order and complexity, which they are; then there must be a Darwinian algorithm operating on something inside them, and that something we shall call memes.

"The Darwinian algorithm can run whether you have got digital or analog information," she says. "It will run better and with higher fidelity if it is digital. But it can run over analog information."

Language is an analog medium, not a digital one, but Blackmore sees the emergence of language as a prime candidate for memetic evolution. "There is a problem of design in language: not just at the deep level of universal grammar, but at the observable level of the languages we actually speak. Why are there so many languages, and why do they stay so separate?" She cites research to show that after 40 years of mass television, the differing regional vocabularies of Britain are more divergent than before. Something is clearly combating the homogenizing effect of TV, and she believes it is the force of memetic evolution.

"Language allows for more accurate copying of thought as it grows more precise. Writing makes copying still more accurate, and thus will increase the size of the memesphere," she argues. The Internet is the most recent expansion of this force.

"What's driving it? Is it our genes, or is it our individual interests? Memetics says that actually it is all in the interests of the memes. What has happened with the development of the Internet is a huge step toward high-fidelity copying -- with just enough errors to make evolution possible. We would expect that to happen because it is in the interests of memetic ambition, and it is completely irrelevant to our happiness. All we're doing is acting as a selection environment."

But memes may not need us to survive, any more than our genes any longer need the bacteria in which their ancestors originated. It is not that we will at some stage create artificial life or artificial consciousness, but that it will create successors to us.

"The more inefficient the technology, the more it relies on humans. But as the technology advances, humans become less and less important. Books made humans less important as a medium for the survival of information. We ought to be able to predict from a memetic analysis of what sort of hardware will best propagate the most memes with the highest fidelity -- and that is what we will find ourselves building."

Blackmore and I were both, by this stage, sitting at open laptops, typing and talking in a synchronous overload; and for a moment I suspected that the laptops were using us to communicate, rather than the other way round.

"The point at which it really takes off," she said, "will be the point at which you have robots which directly imitate other robots in really complex ways. Nothing in artificial intelligence does that now, but when it does, we will have truly human-independent memes."

Only we won't have them. It will be the other way round -- if they can be bothered with us.

THE SIX ESSENTIALS? MINIMAL REQUIREMENTS FOR THE DARWINIAN BOOTSTRAPING OF QUALITY

By

William H. Calvin

University of Washington,
Seattle, WA 98195-1800. USA.
WCalvin@U.Washington.edu

Abstract

Selectionism emphasizes carving patterns, memes remind us of minimal replicable patterns, but a full-fledged Darwinian process needs six essential ingredients to keep going, to recursively bootstrap quality from rude beginnings. While there may be situations ("sparse Darwinism") in which a reduced number suffice, another five ingredients, while not essential, greatly enhance the speed and stability of a Darwinian process. While our best examples are drawn from species evolution, the immune response, and evolutionary epistemology, the Darwinian process may well be a major law of the universe, right up there with chemical bonds as a prime generator of interesting combinations that discover stratified stabilities.

1 Introduction

Since Richard Dawkins' *The Extended Phenotype* [7] got me to thinking about copying units in the mid-1980s, I have been trying to define a cerebral code (the spatiotemporal firing pattern that represents a word, image, metaphor, or even a sentence) by searching for what can be successfully replicated in the brain's neural circuitry, a minimum replicable unit.

I indeed found such circuitry (it implies that the firing pattern within several hundred minicolumns of neocortex, contained in a 0.5 mm hexagon, is such a copying unit). But to explore creativity in higher intellectual function, I wanted to see if the resulting copies could compete in a Darwinian manner, the process shaping up quality as it goes. And that forced me to try and boil down a lot of evolutionary biology, attempting to abstract the features that were essential (for what I came to call "the full-fledged Darwinian process") from those that merely contributed to speed or stability.

This isn't the place to describe the neural outcome - it's in my book *The Cerebral Code* [5] and, more briefly, in the seventh chapter of my other 1996 book, *How Brains Think* [4] - but this does seem an appropriate place to review what I started calling "The Six Essentials." They seem applicable to a wide range of problems within memetics (Hofstadter [12]) as the field attempts to cope with evolutionary models of information transmission. For a more general history of memetics, see the useful bibliographies in [note 1]; I will only mention a few (mostly cautionary!) contributions from neuroscience along the way.

2 Selectionism

'Looking back into the history of biology, it appears that wherever a phenomenon resembles learning, an instructive theory was first proposed to account for the underlying mechanisms. In every case, this was later replaced by a selective theory. Thus the species were thought to have developed by learning or by adaptation of individuals to the environment, until Darwin showed this to have been a selective process. Resistance of bacteria to antibacterial agents was thought to be acquired by adaptation, until Luria and Delbrück showed the mechanism to be a selective one. Adaptive enzymes were shown by Monod and his school to be inducible enzymes arising through the selection of preexisting genes. Finally, antibody formation that was thought to be based on instruction by the antigen is now found to result from the selection of already existing patterns. It thus remains to be asked if learning by the central nervous system might not also be a selective process; i.e., perhaps learning is not learning either.' Niels K. Jerne [15]

The term "selectionism" covers a wide range of cases, ranging from fancy biology with sexual selection to examples that are called "selective survival" because they lack any notion of replication. Brain development offers many examples of this simple end of selectionism. The environment affects survival of cells and their interconnections, and thus helps to create patterns during development (so-called "epigenetic factors in development"). For example, the neural development of a single individual exhibits an enormous overproduction of connections between neurons. Most such synapses (and even long axon branches) disappear, raising notions of selective survival (J. Z. Young's 1964 proposal, that synapses were selectively weakened, was what started this whole line of reasoning [note 2]).

Neurons themselves are also overproduced and die. This again might allow memories to be stored by a carving process (that was Dawkins' 1971 proposal [6]) but it turns out that most neuron death occurs during gestation.

If the removal of connections or cells is carried too far (a common problem in carving wood blocks for printing), there may be no way back (unless, of course, unmodified copies survive elsewhere). Selective strengthening of interconnections, in the face of a culling process, probably accounts for most neural examples of selectionism. Quality can emerge from such carving or selective strengthening. For example, the perception of a speech sound involves the creation of a prototype category that standardizes the meaning despite a range of variations, and selective survival of synaptic connections within a neural feltwork is thought to contribute to categorical perception. But - and this is the important point for memetics - there is nothing recursive about this type of quality enhancement. Which of the selectionist examples should also be called "Darwinian"? I won't review the Darwinian claims except to note that, if we are to blame anyone for the frequent confusion of selective survival with the full Darwinian process, we would have to start with Charles Darwin himself, who named his multipart theory (more in a minute) to emphasize one particularly novel aspect: Natural Selection.

I don't want to seem to be prescribing what's "Darwinian" and what isn't, but I think that we must be cautious about ascribing recursive bootstrapping of quality (what I take to be the heart of the

matter, what makes evolution so interesting) to any process that has a few elements of the process that Darwin and followers have worked out over the last 160 years. Simulations may eventually demonstrate a semidemihemiquasi-Darwinian bootstrap, another self-organizing process that gets better and better - but, until the capacities of sparse solutions are well demonstrated, caution is in order.

3 Sparse Darwinian Possibilities

There are two "halfway houses" which may prove to be more interesting than environmental carving of patterns. First, since brain development (to continue the earlier story) is never really over (it just slows down, and the gene repertoire may shift), and since new synapses may form during adulthood, one is initially reminded of a biological population with replacement and growth - and Darwinian shaping up. But observe that there isn't a pattern being replicated with variations; there isn't a population of such patterns competing with other patterns, etc. - which is what population usually means, not merely a number of constituents comprising the pattern being carved.

While Gerald Edelman [note 3] has such a population lacking patterned individuals, he goes beyond selectionist carving in an interesting, nontraditional way: he has a notion of interacting maps, that shape up one another in a manner rather like the sometimes creative back-and-forth interactions between author and editor (my analogy, not his - as is my perhaps shopworn name for it, revisionism). I have a difficult time identifying either an individual unit, or a distinctive copying mechanism for it, in Edelman's lots-of-neurons notion of a "population," even if his re-entrant loops are reminiscent of generations. His differential amplification via re-entrant loops, however, is undoubtedly an important process (I particularly like it for the consolidation of episodic memories).

On closer inspection, neither developmental patterning nor Edelman's reentry fits my concept of Darwin's process. Populations - in ecology and evolutionary biology and immunology - usually involve lots of patterned individuals somehow making near copies of themselves, all present at the same time, interacting with one another and with the environment.

Yet analogies always leave something out; we don't expect them to be perfect fits, exactly the same thing. As the poet Robert Frost once said, we have to know how far we can ride a metaphor, judge when it's safe [11]. That's exactly our problem in memetics, and why Edelman's notions have proved controversial. When, then, are we forced to ascribe, to a candidate such as developmental patterning or reentry, the potential for the recursive bootstrapping of quality that we associate with Darwin's process, which we regularly see operating on the biological species and the antibody?

To approach an answer to that question, it will be useful to enumerate what has contributed to Darwin's process, while trying to strip it of the biological particulars - and then ask how well it could limp along with a reduced number of components (what I've started calling "sparse Darwinism").

4 The Full-fledged Darwinian Process

The six essentials aren't a settled issue. What I was aiming for, however, were the essential ingredients of an algorithmic quality-improvement process [see consolidation], stated in a way that didn't impose a lot of biological preconditions. I wanted, for example, to avoid making use of the genotype-phenotype distinction, or a universal translation table like the genetic code; I wanted to describe a process, not make an analogy. John Holland's computational technique [13] known as the "genetic algorithm" comes close to what I had in mind, but Holland was trying to mimic recombination genetics in a computational procedure for discovering solutions, and I wanted to abstract more general principles that avoided the presumption of recombination. Since many of us think that (properly defined) the Darwinian process is a major law of the universe, right up there with chemical bonds as a prime generator of interesting combinations that discover stratified stabilities [note 4], we want it to be able to run on different substrates, each with their own distinctive properties that may, or may not, correspond to those seen elsewhere. So our abstraction should fit the species evolution problem, as well as the immune response, but also be independent of media and time scale. Here, paraphrased from The Cerebral Code [5], is what I ended up with:

There must be a pattern involved.

The pattern must be copied somehow (indeed, that which is copied may serve to define the pattern). [Together, 1 and 2 are the minimum replicable unit - so, in a sense, we could reduce six essentials to five. But I'm splitting rather than lumping here because so many "sparse Darwinian" processes exhibit a pattern without replication.]

Variant patterns must sometimes be produced by chance - though it need not be purely random, as another process could well bias the directionality of the small sidesteps that result. Superpositions and recombinations will also suffice.

The pattern and its variant must compete with one another for occupation of a limited work space. For example, bluegrass and crab grass compete for back yards. Limited means the workspace forces choices, unlike a wide-open niche with enough resources for all to survive. Observe that we're now talking about populations of a pattern, not one at a time. The competition is biased by a multifaceted environment: for example, how often the grass is watered, cut, fertilized, and frozen, giving one pattern more of the lawn than another. That's Darwin's **natural selection**.

New variants always preferentially occur around the more successful of the current patterns. In biology, there is a skewed survival to reproductive maturity (environmental selection is mostly juvenile mortality) or a skewed distribution of those adults who successfully mate (sexual selection). This what Darwin later called an **inheritance principle**. Variations are not just random jumps from some standard starting position; rather, they are usually little sidesteps from a pretty-good solution (most variants are worse than a parent, but a few may be even better, and become the preferred source of further variants).

Neural patterning in development is a sparse case: just a pattern and a multifaceted environment. There is no replication of the pattern, no variation, no population of the pattern to compete with a variant's population, and there's nothing recursive about achieving quality because there's no inheritance principle.

5 Example: History as a Darwinian Process

History qua history - what it includes, what it leaves out, and how these change over time - provides us with a memetic example of these six essentials at work. Of the many happenings, some are captured in patterned sentences that describe who did what to whom, why, and with what means.

Some of these patterns are retold (copied), often with little confusions (variation) and confluences (superpositions). Alternative versions of stories compete for the limited space of bookstore shelves or the limited time of campfire storytelling. There is a multifaceted environment that affects their success, the association of the described events to those of everyday life. In particular, the environment contains mental schemas and scripts; as Aristotle noted and all four-year-olds demanding bedtime stories seem to know, a proper narrative has a beginning, middle, and end - and so "good stories" fare much better in the memorized environment. (Especially those conveyed by historical novels that strengthen the narrative aspects!) Finally, because historians rewrite earlier historians, we see Darwin's inheritance principle in action: new variations are preferentially based on the more successfully copied of the current generation of historical stories, and so history has a drift to better and better fits to language instincts (such as chunking and narratives) because current relevance is shifting and ephemeral.

After many generations, only those stories of timeless relevance are left alongside the likely-ephemeral contemporary ones.

Quality emerges, in some sense, as in the way that the nine-part epic tales studied by Misia Landau (youth sets out on a quest, fails, returns, sets out again with a helper, survives a new set of trials and tribulations, finally succeeds and returns home, and so on [12]) seem to have emerged in many cultures from the retelling of simpler narratives, generation after generation. Our modern origin stories, the anthropological scenarios about human ancestors during the tribulations of the ice age climate changes, are even said to follow the epic template! Can history, as we know it, run on a reduced set - say, without the inheritance principle? (Imagine storytellers always reviewing a videotape before telling the story again, so variations were always done from an unchanging "standard version.") Certainly, a pattern that copied and varied, with retelling biased by resonances with current memories of the current population, would be impressive - but the anchoring of the center of variation to the standard version would keep stories from drifting very far and prevent the recursive bootstrapping of quality.

Suppose that, instead of eliminating inheritance, we loosened the environmental influence - say, individuals' memories [see episodic] for unique episodes faded within a year. The often-told tales would simply drift, adapting to current concerns, losing those of the antepenultimate generation. It would be about like the whale songs that drift from one year to the next. What you would lose,

lacking a good memorized environment that persisted a lifetime to overlap several generations, would be shaping up of quality (those timeless stories with universal relevance, the resonance with episodes recurring only twice in a lifetime, and so forth).

My first "knock-out mutation" sounds, of course, like what we try to train scholars to do ("Avoid secondary sources! Read the original!"), while my second is merely an exaggerated version of the ahistoricism of preliterate societies (the Navajo emigrated from the Yukon to the American Southwest about 500 years ago, but this great migration has been lost to them, recovered only through a linguistic and genetic analysis of the Athabascan peoples). History, however, is not merely the retention of facts: it involves detecting patterns and attempting to understand them - and this involves making good guesses and refining them. That intellectual endeavor is, I suggest in *How Brains Think* [4], another full-fledged Darwinian process.

Competition between concepts is, of course, one of the ways in which science advances; evolutionary epistemology (Mayr [17]) treats this as a Darwinian process. The advance of science differs from ordinary history because the environment biasing the competition between concepts involves a broad range of testing against reality.

6 Nonessentials: Catalysts and Stabilizers

There are another five features that, while not essential, do notably influence the rate of evolutionary change:

Stability may occur, as in getting stuck in a rut (a local minimum - or maximum - in the adaptational landscape). Variants happen, but they're either nonviable or backslide easily. Systematic recombination (crossing over, sex) generates many more variants than do copying errors and the far-rarer point mutations. Or, for that matter, nonsystematic recombination such as bacterial conjugation or the conflation of ideas.

Fluctuating environments (seasons, climate changes, diseases) change the name of the game, shaping up more complex patterns capable of doing well in several environments. For such jack-of-all-trades selection to occur, the climate must change much faster than efficiency adaptations can track it (more in a minute).

Parcellation (as when rising sea level converts the hilltops of one large island into an archipelago of small islands) typically speeds evolution. It raises the surface-to-volume ratio (or perimeter-to-area ratio) and exposes a higher percentage of the population to the marginal conditions on the margins.

Local extinctions (as when an island population becomes too small to sustain itself) speed evolution because they create empty niches. The pioneers that rediscover the niche get a series of generations with no competition, enough resources even for the odder variants that would never grow up to reproduce under any competition. For a novel pattern, that could represent the chance to "establish itself" before the next climate change, for which it might prove better suited than the others.

There are also catalysts acting at several removes, as in Darwin's example of how the introduction of cats to an English village could improve the clover in the surrounding countryside: The (i) cats would (ii) eat the mice that (iii) attack the bumble bee nests and thus (iv) allow more flowers to be cross pollinated. (You can see why I call these the "Rube Goldberg Variations.")

7 The Augmented Darwinian Set

Although a Darwinian process will run without these catalysts, using Darwinian creativity often requires some optimization for speed. In the behavioral setting I analyze in my two 1996 books, quality must be achieved within the time span of thought and action.

Accelerating factors are the problem in what the French call avoir l'esprit de l'escalier - finally thinking of a witty reply, but only after leaving the party. Some accelerating factors are almost essential in mental Darwinism simply because of the time windows created by fleeting opportunities, and so this "augmented Darwinian set" may also prove to be important for other memetic applications of the universal Darwinian process.

8 Discussion

I am proposing a standard Darwinian set (six ingredients, in my formulation), with nonstandard cases often described via the sparse and augmented sets. As with Edelman's reentry, some cases may be both sparse and have a novel feature like revisionism (mixed cases). I was delighted to discover that my (neocortical circuitry) candidate process was not only capable of implementing all six essentials, but stability and the four catalysts as well.

At what point can we carry over the traditional implications of the best-studied case, the species-evolution Darwinian process, to a candidate process? My present answer would be: When the six essentials are present, and no obvious stability or relative-rate issue seems to be precluding "progress," we are then entitled to predict that our candidate process is capable of repeatedly bootstrapping quality.

The extent of "coverage" of memetic theories varies widely. For example, I was able to spend much of my last chapter of *The Cerebral Code* discussing the Darwinian implications of minor circuit malfunctions for a broad range of pathophysiology such as seizures, hallucinations, delusions, amnesia, déjà vu, and so forth. My point is that candidate processes in other memetic fields are also likely to be judged by similar nonevolutionary considerations, so we must remember that possessing the six essentials is only a "threshold" consideration, mostly relevant to the sorts of quality that can be bootstrapped - and for how long that improvement can continue.

8.1 Stratified Stability and Relative Rates

One coverage issue that seems relevant, however, is whether new levels of organization emerge from the candidate evolutionary process. Can, for example, a candidate process form categories?

Can it progress to evolving analogies [note 5] or metaphors? Are these new levels ephemeral, or stable for awhile?

Jacob Bronowski spoke of "stratified stability" and observed [2] , "The stable units that compose one level or stratum are the raw material for random encounters which produce higher configurations, some of which will chance to be stable....Evolution is the climbing of a ladder from simple to complex by steps, each of which is stable in itself." Does the process self-limit when reaching an angle of repose, so that piling on another layer is self defeating? Does the process backslide in a catastrophic manner, requiring something like the Weismannian barrier between genotype and phenotype to provide a ratchet?

Relative rates play an important role in any process involving change, one that can trivialize or magnify. Relative rates of expansion are the major principle underlying most household bimetallic-layer thermostats, and it is a familiar principle in development (the way curved surfaces are made is to have two sheets of cells in contact, one growing faster than the other). And we've already seen two examples here: the history example of episodic memories that faded quickly when compared to the generation time and lifespan, and again in (Hofstadter [9]) where climate changes had to be much faster than adaptations could track, if jack-of-all-trades abilities were to accumulate in the face of competition from lean, mean machines.

8.2 Repackaging the Essentials

Someone will surely try to condense my six essentials to a phrase more memorable than "a pattern that copies with occasional variation, where populations of the variants compete for a limited workspace, biased by a multifaceted environment, and with the next round of variations preferentially done from the more successful of the current generation." Indeed, Alfred Russel Wallace did a pretty good job back in 1875 ("...the known laws of variation, multiplication, and heredity... have probably sufficed....") [14] .

It's just that I make explicit the pattern, the work space competition between populations, and the environmental biases. As noted in [note 4], I'm trying to avoid lumping where I know that splitting is going to be required later, to deal with some important partial cases. Wallace shows us that only three items cover a lot of essential ground, and there are surely other profitable ways to split and lump, if context allows the inference of other factors. A list of essentials - at least one that aspires to some universality - can't omit the context, can't skip over the potential confusions. Bronowski once observed [1] that, even if six sentences might serve to sum up one of his lectures, the rest of the hour was really essential for disambiguating the meaning of those summary sentences. The name of the game here isn't compression but abstraction, an abstraction that is just general enough to cover a number of situations that differ widely in media and time scale - but not so abstract as to lose important associations.

Of course, all the definition in the world can be upset by one little existence proof, a simulation of a self-organizing quality bootstrap that runs on a different set of principles. Until then, we are simply trying to clarify our thinking about the creation-of-quality process we know best, the one first stumbled upon by Charles Darwin.

Notes

Memetic history is covered in a number of places; see, for example, the excellent webbed bibliographies of Barry McMullin, Hans-Cees Speel, and John S. Wilkins.

John Z. Young, *A Model of the Brain* [19]. His *The organization of a memory system* [20] introduces the mnemon concept in which weakened synapses serve to tune up a function. A later version is his *Learning as a process of selection* [21]. The modern chapter of mental darwinism starts in 1965 with Daniel C. Dennett's D. Phil. thesis, published as [8] but it all began more than a century ago with William James, *Great men, great thoughts, and the environment* [14]. Gerald M. Edelman, *Neural Darwinism* [9] and *Bright Air, Brilliant Fire* [10] (especially chapter 9 where he addresses his critics). Reviewed by me in [3].

In introducing stratified stability, Bronowski says: "Nature works by steps. The atoms form molecules, the molecules form bases, the bases direct the formation of amino acids, the amino acids form proteins, and proteins work in cells. The cells make up first of all the simple animals, and then the sophisticated ones, climbing step by step. The stable units that compose one level or stratum are the raw material for random encounters which produce higher configurations, some of which will chance to be stable.... Evolution is the climbing of a ladder from simple to complex by steps, each of which is stable in itself." [1]

In searching for Hebb's cell assembly (a committee of neurons whose firing represents a color, word, thought, etc.), I looked for neural circuitry in the brain that was capable of copying spatiotemporal firing patterns. The top layers of the newer parts of cerebral cortex indeed have recurrent excitatory circuitry that should produce synchronized triangular arrays of neurons which extend themselves over a few centimeters, or recruit distant populations via corticocortical pathways. Collections of such arrays constitute a spatiotemporal pattern with great redundancy. The smallest "tile" in this mosaic, which has no redundancy within it, is hexagonal in shape and about 0.5 mm across; it probably has a few hundred independent elements. This is a minimal replicable unit (and a candidate for a cerebral code for, say, a word or concept); a hexagonal mosaic of it can compete with another pattern's hexagonal mosaic for territory in association cortex.

Glossary

Ahistoricism

is discussed in the first chapter of my book, *The River That Flows Uphill*. But Loren Eiseley said it best: "Man without writing cannot long retain his history in his head. His intelligence permits him to grasp some kind of succession of generations; but without writing, the tale of the past rapidly degenerates into fumbling myth and fable. Man's greatest epic, his four long battles with the advancing ice of the great continental glaciers, has vanished from human memory without a trace. Our illiterate fathers disappeared and with them, in a few scant generations, died one of the great stories of all time."

An algorithm

is a simple systematic procedure for solving a problem, usually involving repeated steps, e.g., long division (try multiplying the divisor by two and subtracting; if the remainder is too large, try 3, etc.).

The angle of repose

is a geological term for how steep-sided a pile can become before little landslides remove any further additions.

Bootstrapping

("Pulling yourself up by your own bootstraps") is a term that describes the ability of simple patterns to bring forth more complicated ones. A familiar example is the start-up procedure for a computer: booting involves a simple program stored in a ROM chip that, in turn, reads and starts up the operating system from a hard disk - which, in turn, starts up the application programs.

Episodic memories

are those of unique events, such as a particular conversation; they're much more difficult to maintain than memories of repeated events. **Consolidation** of memory is the often-fallible process of making short-term "volatile" memories into more permanent long-term memories with an enduring structural basis. I suggest, in chapter 6 of *The Cerebral Code* [5], that Edelmanian revisionism, between a hippocampal map and a cortical map, would be a useful way of "learning" (via repeated trials) what was originally only a unique episode and embedding it in neocortex. Like a photographic development process, it is likely that, in the manner of those three-million-year old footprints that were preserved by volcanic ashfall (cement on the fly preventing the usual erosion and backfilling), both culling and fixation are involved in biological memories.

Weismann's genotype-phenotype distinction

in biology is not a necessary condition for a Darwinian process, as recent experiments on "RNA evolution" have shown (there isn't a body that lives and dies, carrying the genes along, but rather patterns directly exposed to environmental selection). Envelopes such as bodies (phenotypes) are an example of stratified stability; they nicely illustrate why strict one-trait-at-a-time adaptationist reasoning is insufficient. Genes often live - and die - in a collection called an "individual," which means that success is often via particular combinations of traits.

TOWARDS A COGNITIVE MEMETICS: SOCIO-COGNITIVE MECHANISMS FOR MEMES SELECTION AND SPREADING

By

Cristiano Castelfranchi

castel@ip.rm.cnr.it

Abstract

After stressing the autonomy of a cognitive agent relative to social influence, and the importance of cognitive constraints in accepting a given meme, we discuss three specific micro-mechanisms for adopting a given behavior; they differ in the interpretation of the observed behavior and in the motives for replicating it. Tomasello's model of cultural transmission is discussed. Special attention is paid to the role of norms in meme spreading, to the role of social identity and membership, and to inter-group differentiation. Principles supporting the diffusion of *know how* are different from principles supporting the diffusion of *know that*. Cognitive constraints for beliefs acceptance are examined. Not only the adoption of a meme but also its diffusion can be the result of a decision by the cognitive agent; different socio-cognitive micro-mechanisms have different macro-results in meme propagation. Those examples and models are aimed at claiming that the agents' minds are the most relevant selective environment for memes. To understand cultural evolution it is necessary to identify the cognitive principles of the success or selection of memes *within minds*. Memetics can only be cognitive; otherwise it is contradictory and non explanatory.

Keywords: memes, cognitive memetics, culture, beliefs, norms, social identity

Introduction

We start from the autonomy of a cognitive agent relative to social influence and the importance of cognitive constraints in accepting a given meme. In this perspective, Tomasello's model of cultural transmission is discussed. On the basis of general principles of cognitive processing (as the role of interpretation and 'understanding' of the input) we introduce three specific mechanisms for adopting a given behavior: 'instrumental adoption' based on means-end reasoning and on practical utility (section 2.); normative adoption, where certain behaviors or values are prescribed by social norms and the agent wants to conform to such norms (section 3.); and the social identity mechanism, where the agent imitates a given behavior of others to be "like them, one of them" (section 4.). Those mechanisms differ one from the other as for the cognitive interpretation of the observed behavior and for the subjective motives for replicating it. Special attention is devoted to the role of norms as spreading memes and as meme-regulators, and to the role of the inter-group differentiation motive. Principles supporting the diffusion of *know how* are different from principles supporting the diffusion of *know that*. Cognitive constraints for belief acceptance are examined (section 6). Finally a more sophisticated model of the cognitive processing of a candidate meme is presented (section 7.) where not only the adoption of a meme

but also its diffusion can be the result of a *decision* of the cognitive agent. Different socio-cognitive micro-mechanisms make different predictions as for their emergent effects; in fact, they have different macro-results in meme propagation. Those examples and models are aimed at claiming that the agents' minds are the most relevant selective environment for memes and the *media* of their transmission. To understand cultural evolution it is necessary to identify the cognitive principles of the success or selection of memes within *minds*. Memetics needs cognitive modeling.

1. Cognitive Autonomy and Mediation in Cultural Transmission

Humans are cognitively autonomous [6; 18], i.e., they have a rather good control over their own mental states, relatively to external social influence. This plays a central role in cultural evolution [13; 17]. One cannot make another believe or do whatever he wants the other to believe or do. One should resort to complex strategies, like education, persuasion, manipulation, etc. in order to deal with the *cognitive constraints*, filters, and mechanisms of the addressee.

Autonomous agents believe something only on the basis of what they believe and wish (section 6.); they decide to do something only on the basis of what they believe and wish; they learn to do something on the basis of their motives and of the *perceived* rewards, and on the basis of cognitive processes like attention, memory, association, analogy, abstraction, etc.

These cognitive constraints decide also of meme adoption and transmission; thus there is a crucial cognitive mediation [17; 8; 10] in memes spreading and inheritance [note 1]. The individual mind with its cognitive processes is the fundamental selection environment for memes. For the great majority of memes, it holds that:

if memes do not win within the mind of the individual, they cannot spread around in the population.

1.1 Limits of these 'cognitive' approach and representations

It is important to keep in mind that 'cognitive' is synonym of 'mental', not of 'conscious' or 'rational'. It is important to analyze and clarify the mental mechanisms of such broad or obscure notions as 'imitation' or 'contagion', but those mechanisms are neither necessarily rational nor conscious. In the following, we will describe different mechanisms in terms of 'beliefs' and even of 'decisions'; however, only the first mechanism has to do with rational instrumental reasoning, and none of them is supposed to be necessarily conscious. However, unfortunately, this is not enough: our framework will keep some rationalistic flavor, because of its formulation in terms of explicit beliefs and goals.

It is worth specifying that:

on the one hand, I do not exclude other -more primitive- mechanisms for imitation or for 'contagion', based on mere automatic rules [note 2]; I simply would like to have some clear model of them in terms of internal processes and devices (rule-based reactive agents, conditioning, etc.);

on the other hand, I admit that my approach is limited: one should provide a more complete theory, for example about the role of affective reactions, on intuitive appraisal in adopting ideas, attitudes or behaviors, and suggest a theory of implicit beliefs and goals in memetic processing. Even the notion of 'decision' can be interpreted at different levels of cognitive complexity: at a more 'procedural' level, for example simply as a test, an "if/then/else" step in a flowchart; or at a more 'declarative' level, as a conscious deliberation based on explicit evaluations. The proposed mechanisms are presented in a very explicit and propositional way, but their really important message is as follows: mental interpretation and internal representation (for example, in declarative terms) are crucial in the memetic process; there are different cognitive mechanisms accounting for the acceptance and the spreading of a meme by an agent.

1.2 Diffusion vs. Tradition

An interesting model of cultural transmission that gives some room to cognitive processes is Tomasello's ratchet model, (see Appendix) although it is too focused on learning and children. It underestimates the role of synchronic or horizontal cultural diffusion as a fundamental condition also for an efficient diachronic or vertical diffusion (tradition, inheritance). Transmission of cultural features does not occur only from one generation to the next (like in this model). In fact in order to spread from one 'generation' (and not from one individual) to another, the trait is supposed to be diffused within the first generation. Clearly:

the diachronic transmission is function of the diffusion in a given population (and vice versa)

'diffusion' both in terms of extension and duration: the greater the number of individuals in a given population that are vehicles of a given cultural trait (behavior, idea, artifact), and the longer the period of their having/exhibiting/using such a meme, the greater the probability of the same meme in the next generation of the same population.

(conversely, transmission from a previous generation to a new generation, i.e. inheritance, is one of the causal factors that strongly affects the diffusion of a given trait in a given population).

Also considering the synchronic diffusion, the notion and mechanism of 'imitative learning' - although in the rather clear (and cognitive) version of Tomasello - is not enough. The problem is *why another adult individual should 'adopt' or 'accept' a mental representation, a behavior, an artifact from another individual or group.*

We believe that there is no unique answer, that is, there are several cognitive mechanisms (beliefs + motives) through which this happens. In the next sections we will examine some of these different mechanisms, but first we have to describe a *cognitive-mediation* view of 'imitation'.

1.3 A basic model of replication in cognitive agents

A cognitive agent has three crucial and defining features (among others):

i. Cognitivism

Vis a vis information, events, situations, inputs in general, the agent interprets them, and reacts in some way not to the event or situation but to the subjective perception of it; i.e., the mental representation of it; the meaning the event has in its meaning and value system; it reacts to the meaning that it attributes to it. [note 3]

ii. Reasons

A cognitive agent activates, selects, prefers, pursues, gives up goals on the basis of what it believes [6]. In other words, it has 'reasons' for what it does.

iii. Purposes

A cognitive agent is a goal-directed agent (endowed with intentions, planning, and deliberation abilities, ...); its behavior is in fact 'action' aimed at certain anticipated results (mental representations) and is controlled and motivated by them (these representations).

From these basic assumptions it follows a rather obvious and simple model of the replication of behaviors in Cognitive Agents. As stressed by Conte [17] "behavior does not spread automatically but through the agent' mind":

agents have to observe a behavior; to interpret/understand it; and then to have their own motives and reasons for performing (and store and repeat) such a behavior.

Only on the basis of their understanding and of their motives and reasons they can replicate the same behavior or some accidental or adjusted variation of it.

Figure. 1

It is important to notice that

a) the behavior is 'on purpose' but its replication is not necessarily intended or motivating [note 4];

b) analogously, the 'spreading' effect is not necessarily known or intended by the agent.

1.4 Three mechanisms for meme adoption and replication

In the following sections we will give three examples of the application of this model: what we will call the means-ends or instrumental reasoning; the normative reasoning and compliance; the Identity or membership based reasoning.

These three mechanisms are different realizations of the same abstract model (Fig. 1) with its crucial steps. They differ one from the other precisely because the inference/interpretation (understanding) of the observed behavior is different; and reasons and motives for replicating it are very different one from the other. They could be applied to one and the same observed behavior, while producing quite a different cognitive and social processing [note 5]. Let us adopt as our working example the following one: suppose we are in a new country and culture and we observe that they -unlike us- use fork and knife for peeling fruit. The following are three possible interpretations.

2. Instrumental Adoption: the 'practical problem-solving' mechanism

This mechanism applies to what we could generally call 'means' that is actions, plans, recipes, rules, procedures, tools (*Know How transmission*)

Tomasello's answer to our starting question (*why should another adult individual 'adopt' or 'accept' a mental representation, a behavior, an artifact by another individual or group*) is the following one. Imitative learning of a feature *x* is not simple emulation or echoing, but it is based on some *understanding* of the purposes and reasons of the model *M* exhibiting it.

Let's characterize this mechanism as follows:

Given an Adopter *A*, a trait *x* and a Model *M*, conditions for 'ADOPT *A* *x* from *M*' are:

Bel A (Use M x for p) [note 6]

which implies that **Bel A (Goal M p)** and

Bel A (Bel M (Good-for x p)) [30] [note 7]

Bel A (Good-for x p) (shared *evaluation* of the mean)

Bel A for-all y (Better x y for p) [note 8]

Goal A p

Then 'Adopt A x for p' means that:

A stores beliefs about x as a good-means for p in its 'know how' for p. When goal p becomes active, A will consider x as a possible means (plan, action, tool) for p, better than others, and then probably A will use x, as M does.

In the fruit example the agent reasons as follows: "In this way, one doesn't dirty one's hands and face! It's a good solution: I'll do the same". The Adopter has *reasons* (the evaluation of y) and *motives* (its need and problem) for adopting and replicating the behavior.

In sum, *individuals accept new behaviors, plans or tools as better solutions for their own problems, as good means for their goals*; the group diffuse and preserve (memorize) and transmit the best (discovered) solutions. This is also (one of) Hayek's view(s) about tradition, its validity, and unintended cooperation in constructing social institutions, rules, and technology (what Tomasello [36] calls the third kind of sociogenesis of culture, i.e. of its cooperative construction).

This 'practical problem-solving' mechanism seems very close to what Hedstrom [27] calls 'rational imitation' [note 9]. However, it is worth stressing that the agent's understanding of the intention and plan of the observed Model, and its evaluation of the use and advantage of the new behavior or method it is not a trivial problem [15].

Notice that for this kind of "imitation" even one single example/model can suffice. However, usually the greater the number of sources of a belief the more credible that belief (section 6.). In the same vein, the greater the number of agents who adopt a certain "solution" (tool, recipe, plan, etc.) the more influential that solution becomes: the more it is diffused the more it looks validated and good.

3. Normative Adoption: The normative character of cultural transmission

It is underestimated that cultural transmission - including the *adoption* move - has a very strong 'normative' (and more precisely 'prescriptive') character. It is not simply matter of the Adopter's interest and initiative. Also M and the group care about such an adoption. It is not simply a matter of technical/practical reasoning ("is this a better solution for my needs/problems?"). Completely different, non-technical criteria guide the adoption of cultural features, like a behavior in given circumstances, or the use of a given plan or tool. Culture is a set of expectations and prescriptions on the members of the group: each member expects and wants the others behave according to cultural traditions (prescriptions) about what to do (think and feel), when and how.

The satisfaction of those expectations (social approval motivation, membership-collective identity motivation) and the conformity to those norms (for several motives [18]) is one of the main reasons why people adopt a cultural trait when entering a given culture.

Again, this presupposes a rich cognitive representation, an 'understanding' of the others' minds and behaviors: more precisely, it presupposes the *recognition* of such a Model, example, expectation and advice *as a norm*, and its normative adoption [18].

By adopting x, A knows and intends to conform to a norm, and -by doing so- it confirms it and the authority of the group.

This is also a message that A's behavior is sending to the others: "I intend to 'respect' the norms, our habits and traditions, and our authorities" (3.1). This 'message' can be the only real function of the behavior that becomes completely 'ritual' and loses any practical function and reason. For example, why not cut fish with a knife? this is just a ritual adhesion to a custom.

The normative mechanism

Bel A (Norm x on group Y)

Bel A (member A of Y)

Goal A (Adoption of N impinging on A)
(for several possible motives/ higher goals)

Goal A (Adopt A x)

In the fruit example the Adopter's reasoning is as follows: "Probably this is a social norm, maybe handling fruits is considered a sacrilege. I had better respect this custom or rule".

Notice that the Adopter also believes that everybody does so; or at least that it is very diffused. In fact,

a behaviour diffused in a group/population is more likely to be interpreted (recognised) as a norm of that group.

This as for its *recognition* as a norm. Moreover, as for replication (in case of norms: *obedience*)

the more the agent observes that the norm is respected, the more the agent is leaning to conform to it (diffusion).

Among the motives for adopting a norm (obeying it after and because we recognized that it is a norm) there are not only social approval and sanction avoidance, but also possible 'terminal' motives like "norms must be respected". There can also be a motive like: "to make others conform to the norm: i.e. to be a M for the others". In this case the memetic *function* of conforming to a norm becomes an explicit intention in the mind of the agent [9; 11].

3.1 Norms & Memes

On the one side, *memes spread for prescriptive-normative reasons*, and on the other side, *norms are themselves memes*, aimed at spreading around in a given group or population, and at being adopted and shared by its members.

Thus, Norms are META-MEMES: they are memes for regulating the conformity to and the *spreading* of behaviors, goals, ideas; they provide Models and prescribe who should or can do what.

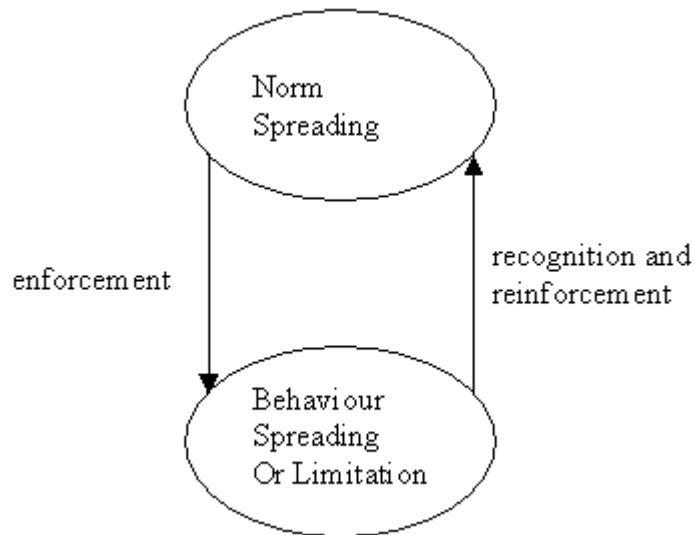

Figure. 2

When conforming to a social or legal norm the agent is at the same time acknowledging the authority issuing the norm, and reinforcing both. In fact, the most respected is an authority the most respect-worthy it is. As we said, the more respected is a norm the more difficult it is to not recognize it as a norm and to deviate from it.

Particularly interesting in this perspective is the notion of 'authority' which is a specifically memetic notion. In fact 'authority' stands for the influential role, the leading impact of a memetic source on the other agents. Either it is the role of a Model among a group of 'followers' who imitate her/his behavior or absorb her/his ideas [note 10] because of its prestige or competence; or it is the role of a norm-issuing agent who, by norms and commands (prescriptions), shapes the behaviors of subject agents.

Norms are not only prescriptions, but also permissions and *prohibitions*. This means that while in some meme-adoption the individual can feel free, in others it has an obligation, and other meme-adoptions are simply forbidden and would imply a violation. Thus norms create real (mental) barriers to the diffusion of a given meme. Consider such example as the attitude towards contraceptives in catholic countries and its effects, or the moral values against the use of drugs acting as defensive mechanisms in some social groups, or the resistance to the penetration of the western 'civilization' in Islamic countries. *Moral barriers* (prohibitions) can be very effective.

4. Identity/Membership: the Social Identity Mechanism

Several authors (including Tomasello [36]) agree about the fact that social/cultural identity and identification with the others play a crucial role in cultural transmission. In Tomasello's model this is due to the crucial role that in true imitative learning is played by the *understanding* of the mind (intentionality) of the other, and this understanding seems due to the projection -by the

child- of his subjective experience, thanks to the belief/feeling "he is like me" (p. 14). This is an interesting view but it is rather limited.

On the one side, in fact it is possible to ascribe mental states (especially in adults) without identification, empathy or whatever projection of our subjective experience; just as powerful predictive models of special 'agents'.

On the other side -and this matters here- *identification* plays a much more important role as feeling, belief and desire of membership in a category and of acceptance in a group, that is as personal 'social identity': "I am, I feel I am an X"; "I am *like them*, one of them".

In both cases ("he is like me" and "I am like them") there is some form of identification, but they are not equivalent. The analogical movement is in fact reversed: in one case, the others are assimilated to me and some of my features are ascribed to them; in the other case, I'm assimilated to them, and their features are 'transferred' to me.

Social Identity Mechanism

If I believe and/or want to be "one of them" (males, Italians, researchers, etc.), if this is part of "my identity", and

I believe that certain features are needed

- either to belong to that class or category X (*weak membership*),

or

- to belong to a given group via their 'recognition and acceptance' (*strong membership*) ;

or

I believe that certain manifested features (behaviors, attitudes, use of artifacts, etc.) are *symbols* of this membership (and status) and are used for recognizing a person as "one of them", [note 12] and

I want to send such a message and to be recognized as "one of them"

then

I want to ADOPT those features from/of that category or group in order to:

be an X;

be accepted as "one of them";

be recognized as "one of them"

feel I am one of them and recognize myself as "one of them".

In the fruit example the implied reasoning would be something like: "this is a sign of distinction of an elite, a sign of membership to a special group; I want to be like them (distinguished) or one of them (elite)".

Notice that the Adopter also believes that not anybody does so, but just a sub-group.

4.1 Identity Differentiation or Hostility

Since social identities obviously presuppose distinction, differentiation, and even hostility and conflicts, the belief and the goal of "being an X; being one of them" necessarily implies

the goal of "not being a Y", "not being like them". [note 13]

We call this goal 'Social Identity Hostility'. It plays a very important role (as the previous Identity assimilation) in cultural transmission. On the one hand,

this is a motive for *NOT Adopting* a given cultural trait, for not conforming and personally rejecting it;

it is a possible motive for *actively fighting against the diffusion* of this trait in the population (for my sons, friends) and against the expansion or existence of the other group members, ideas, behaviors (these are *cultural wars*).

Thus there can be a motivated resistance and even active opposition against the spreading of a trait. In other words we are far from a notion of 'contagion', and we see again the *selection process* as a *mental process*, and as deciding in favor or against of the trait adoption and determining the macro-spreading or not of a given behavior.

On the other hand,

this can be a motive for *not propagating* in some direction, *not revealing* our 'knowledge' or features, in order to protect our difference or our superiority (and power).

Finally,

this can be a motive for *innovation*: in order to re-establish a distinction from other classes or groups (for example higher class distinctive behaviors or symbols) new distinguishing features could be necessary.

As for the importance of the Distinction force (motives) in a dialectic relationship with the Conformity force, see Simmel's view on fashions [34; 3; 32].

4.2 Cooperation and conflict between the practical, normative, and identity-based adoption mechanisms

Those different motives and mechanisms for adoption, preservation, and transmission of memes can converge and cooperate with each other but they can also be in conflict. For example the normative mechanism and the practical one converge when it is both useful in practice and socially prescribed to adopt a given behavior. They are in conflict when the individual, on the one hand, is motivated to conform to the tradition, or to the expectations and approval of the others, while, on the other hand, the new solution looks more efficient for its practical purposes.

Also between the normative and the identity-based mechanisms for meme spreading there can be a conflict, but usually they cooperate. In fact, as we said, membership and social identity are strongly value and norm based, and to be an accepted member of a group one must and want to conform to the group values and norms.

Notice that the 'problem solving' mechanism is both a mechanism for *conservation* (until a better solution appears) and for *innovation*: "it is new but since it is better I will change and adopt it". By contrast, the normative mechanism or the conformist motive, seems only useful for conservation of what is already a norm in the group; it introduces something new only for a learning individual, not as innovation.

It is true that norms also emerge spontaneously and bottom-up, and individuals can create (and even intentionally propose) new norms. However, the motivation for creating a new norm is not the same as that for adopting a norm; while the motivation for finding a better solution is the same as that for adopting a better solution.

5. Perceived Diffusion and Actual Diffusion

As we saw, in all the previous cases the behavior adoption and its replication by the individual are influenced by its *perceived diffusion*, while actual diffusion -in turn- depends on individual agent adoption:

Figure. 3

As we said, the individual mind is not the *only* selecting environment; for example, diffusion in population plays a role by itself:

DIFFUSION ==> DIFFUSION

For example the probability of survival of a given belief or behavior after a catastrophe destroying a population or a culture, or after an invasion, is greater when that meme is very diffused in that population.

However in the above mentioned mechanisms the 'diffusion' factor passes *through the individual mind*:

Actual DIFFUSION==>(perceived-diffusion/ interpretation/ adoption) ==> Actual DIFFUSION

The fact that in all these mechanisms (especially the first two) adoption and replication are strongly influenced by *perceived diffusion* shows that the notion of 'social proof' [16] is a vague and broad category covering different processes, not a single and precise mechanism (as proposed for example by Hedstrom [27]). Moreover, the role of the perceived diffusion in diffusion process is a nice example of '**immurgence**' in social dynamics: i.e. of the feedback of complex macro-level effects on the micro-level and in particular it is an example of the role of the mental representation (partial understanding) of the emerging macro-phenomena [18; 9].

6. Belief Adoption and its Constraints

Those mechanisms (section 2, 3 and 4) mainly refer to behavioral 'imitation' (that in a cognitive agent - whose 'behavior' is goal-directed - means the imitation of goals, and the reasons and motives for adopting those goals). Important special constraints concern the adoption and spreading of *Beliefs*, that is opinions, evaluations, (folk)science, factual knowledge, etc. (***Know That transmission***)

We cannot believe anything we observe or somebody communicates to us. We accept a given belief on the basis of our previous beliefs, of their evidence, supports and sources, and of others psychological factors. Analogously we decide to spread around our opinion or our knowledge for some reason and purpose. To study belief-propagation we have to study the principles of belief credibility and belief sharing. Let us sketch some crucial point of these cognitive mechanisms.

Our knowledge base is not a file where one can introduce new data or eliminate a file-card without altering the other data. Our beliefs are integrated, interconnected and mutually supported: to drop a belief or to add a new one entails checking its coherence with the rest and revise previous knowledge. The belief-belief coherence and support is quite a well studied problem in philosophy and AI (truth maintenance systems; belief revision and updating; argumentation) and in some cognitive agent architecture. There are in fact two schools in belief revision ([26; 24; 22]): the "foundations approach" stressing the importance of supports and justifications of beliefs, and the "coherence approach" modeling logical compatibility and coherence. However, we agree with Doyle [22] that there is no incompatibility between the two models, and that beliefs must be both relatively coherent and justified.

6.1 To accept and to reject; storing vs. believing

As we wrote elsewhere [7] the meaning of 'revising' and of 'rejecting' a belief is quite obscure. One either believes something or she does not believe it. What does it mean to 'reject' a belief or an information [5] (which is not the same)? In our view in many approaches there is a dangerous confusion between memory and knowledge, between storing an information and accepting/believing it. In several models, the belief base is imagined as a memory store plus the coherence constraint. When a new belief arrives it is either coherent -and it is accepted (added)- or it is in conflict with other beliefs. In that case, after a given process, the new belief is either rejected (not stored) or the old knowledge is revised in order to be compatible with the new information. In this simplistic scheme, to 'accept' means both to store and to believe, while to 'reject' means not to believe and even not to store the 'information'. In order to avoid such a confusion and to clarify our interpretation of accepting and rejecting, we will assume *a strong independence between memory and knowledge* (or better beliefs). Quite obviously:

- a) one can remember something she does not believe (and remember that she does not believe it); and
- b) one can forget something she believes.

Thus, when we say that a given information is 'rejected' we mean that the subject *refused to believe it*, but that this information (and its disbelief) is perhaps stored. When we say that an information has been 'accepted' we do not mean that it has just been stored: we mean 'believed'.

It is important to notice that we do not spread around *only* 'believed' information; not only because there are a lot of lies and simulation in human communication and social interaction, but because, for several reasons, we maintain and transmit a lot of non-believed information.

I will not discuss here the function of legends, fiction, play, etc. but, it is important to notice that information passed round as shared knowledge follows different paths and has different filters than information transmitted as fiction; and -of course- they satisfy different cultural functions.

6.2 The decision to believe

In our view, there is a basic postulate for our decision to believe:
Believe only if you have reasons to believe

However, a reliable source is by itself a reason for believing.

In this way the postulate is not too strong [note 14], and does not contradict -in our view- Harmann's claim [26] and some experimental results [25]. In fact, we don't imply that to believe something one has to logically demonstrate it in her/his knowledge base, or find it strongly 'plausible'. We just imply that sources give us reasons to believe -quite automatically- and that these reasons have to be stronger than the possible first hand 'implausibility' of the new piece of information.

Source reliability and belief credibility

On the one side, believing in a source depends on its assumed reliability [note 15]. On the other side,

The Credibility of a piece of knowledge (a candidate Belief) is a function of its sources

The basic principles governing Credibility are the following ones :

1a. If the source is reliable its information is credible and is believed; if it is not reliable its information is not credible and not believed. (In quantitative terms: the more reliable the source the more credible the information provided)

1b. The many the converging (independent) sources, the more credible the information provided

Any convergent source of knowledge 'confirms' the other (in particular: S2 confirms S1, when S2 is a new source for a previous item whose source was S1).

'**Confirmation**' is a fundamental cognitive 'integration' among sources. It consists of the fact that:

a) after the arrival of a 'confirming source' the item (the belief) is stabler, safer, more certain, and we subjectively are more sure and convinced about it;

b) not only the item is more 'credible', but also the confirmed source is more credible, trusted (it is felt as more 'reliable').

Confirmation is a very important psychological phenomenon: when we control or check something we are just looking for confirmatory sources; proactive behavior, expectations, and goals imply some 'confirmation' mechanism; there is a very well studied 'confirmatory bias' in our cognition which is not only due to the cost of revising our knowledge (economic motivation) but also to our need for control and to our need to trust our knowledge and our ability to make predictions [2] (apart from self-deception and defense mechanisms).

The 'independence' of the source is clearly very important for our rationality and for resisting social influence. However, from a psychological point of view we have to admit that people are leaning to accept as confirming and additional evidence also the mere repetition of the same input, and that we do not care so much of controlling the real independence of our social sources (for ex. gossip, or newspapers). This is not so irrational sometimes.

The reliability of the source depends on many different aspects.

As for the social or communication sources, many authors identify two dimensions: *competence* and *trustworthiness*. The first is related to the fact that the content of the information is pertaining to a domain the source can be really expert and informed about.

Other criteria: *importance* and *plausibility*

Of course, number and credibility of sources are not the only criteria for accepting/rejecting beliefs. It is not the aim of this paper to examine the criteria for belief acceptance and revision, however we need to clarify at least partially which are the other factors that contrast or contribute with the sources to the acceptance/rejection of a belief.

Importance

In our view in the literature about belief revision there is a confusion between two properties of integrated beliefs [5] : their *importance* and their *credibility*. They are two distinct dimensions and notions:

a belief could be very important but not very credible; or very credible but absolutely marginal.

By 'important' I mean that it will explain a lot; it will be very *useful for understanding and integrating other information*. 'Credible' means that I have a lot of evidence, sources, supports to believe it. Clearly enough the two aspects are distinct. An integrated belief in a belief network is in fact both supported and supporting: I call *credibility* how much it is supported by external or by internal sources ('plausibility'), and *importance* how much it supports: its explanatory power.

There is a contribution of both 'credibility' and 'importance' in the decision to accept or to maintain a belief. To decide to believe we do not consider only credibility (see later). The fact that a belief is highly 'important' (explains and supports a lot of other beliefs) can be a strong reason for accepting it, and a strong reason for not changing/abandoning it (resistance). In fact abandoning an important belief entails a lot of expensive revisions in our mental map.

Plausibility

To be believed, something should be 'plausible'. Often we resist or reject a new item just because it is not 'plausible'. What is the basis of this kind of evaluation? Why is it a basis for rejection?

Plausibility is *the credibility value assigned to the coming item from inside*. It is evaluated just on the basis of previous knowledge: the same knowledge it has to be integrated with.

Thus, we have two credibility values, one based on external sources, the other based on the niche that has to accept the new item. Metaphorically, one is the value provided by the offering agent that 'gives' the item, the other is the value attributed by the accepting (or refusing) agent. When there is a conflict, and a difficulty to accept the new belief from outside, the conflict is between its 'credibility' and its 'plausibility'. To accept a new belief the plausibility i.e.; the internal source should 'confirm' the external source, and converge with credibility; or, at least, credibility should be stronger than implausibility.

More precisely, **plausibility** is our attempt to derive, infer the new item from our previous knowledge: the more predicted or expected, the more 'plausible'; in other words we are searching an internal source confirming the external one, in order to better 'assimilate' the new information;

at least we would like not to have internal reasons for not believing i.e. implausibility. Implausibility is the result of our attempt to derive/infer the opposite of that item. The first attempt is due to our need not only for knowing 'that' but for knowing 'why' (Aristotle), and for integrating knowledge on such a basis (explanations, reasons,). The second attempt is due to *the necessity to verify if there are conflicts* between the new item and the consolidated knowledge. This would be either a reason for rejecting the item or a reason for revising beliefs and for rejecting (dropping) some old items.

Of course this is a 'normative' perspective; on the psychological side we know that there is experimental evidence that people tend to accept new beliefs without such deep (and long and expensive) controls. Gilbert [25] for ex. has shown that we quite automatically believe all that we comprehend, and that the rejection of ideas comes later as part of a more effortful process. This result should be taken with caution, since Gilbert's notion of 'comprehend' is quite broad. Clearly enough we believe quite automatically, by default [6] provided that there are no overt contradictions, immediate implausibility, or previous reasons to suspect/doubt about the source (see note 12).

External 'credibility' is just one component of the 'acceptability' or 'believability' of an item (its properties that will determine whether it will be believed or not). 'Plausibility' is another component. But even credibility, plausibility and importance are not enough.

There are also other dimensions that interfere with belief acceptance, like 'relevance' and 'likeability' [6; 7]. By 'relevance' we mean how useful, important is a given belief for our interests and goals. By 'likeability' we mean a special aspect of relevance, i.e. the fact that a belief frustrates or satisfies a goal, is pleasant or unpleasant for us. Our belief adoption is not only a rational process; it is also influenced by affective responses - which we cannot address here - such as wishful thinking, defensive mechanisms and self-deception.

6.3 Infra-psychic memetic competition

When and why would two memes be 'in competition' [19; 4]? First of all for merely cognitive-psychological causes. Let us give a couple of examples of infra-psychic memetic competition.

Epistemic unacceptability

As we just saw, meme/belief/idea/plan x can be contradictory with what I already believe. X is 'implausible' to me, i.e. 'unbelievable'. In order to adopt it I should revise a lot of knowledge I have. The new meme (that is attempting to be 'hosted' by me) is in competition with another (previous) one, just for cognitive reasons: I cannot accept both at the same time.

Deontic or Dynamic unacceptability

A completely different case - closer to the previous principle about behaviours ('moral barriers' in section 3.1) but applicable also to mere beliefs- is the following one: X could be believable (acceptable for cognitive coherence and revision reasons) but is unacceptable for moral or

religious reasons (incompatible with my values and interiorised norms), or very disagreeable and painful to me, given my desires and interests.

6.4 Why Sharing Beliefs

What is the use and motivation of sharing beliefs? Is sharing just an effect or is it sometimes an end?

Shared knowledge plays several roles.

On the one hand, shared knowledge is a guaranty of truth. Several independent sources with their own evidence make us more certain about the reality of our beliefs (this is a principle valid even in science). Moreover, the many people -with their coherence and plausibility checking and their control - have accepted a given belief the more it has been cognitively tested and can be believed. As we saw, 'social proof' is an important factor for believing, but it is also a function and a motive for sharing information: testing it, exchanging it, creating a common patrimony.

On the other hand, sharing knowledge is useful for several independent social functions. Coordination, cooperation and organization (working in a common environment for a joint plan) require common knowledge about the task, domain, plan, and context. Group membership and identity require common knowledge: the myth, or the history, or the special competence of the group, etc. Any social interaction and communication requires some common knowledge of rules, scripts [32], roles, etc.

It is important to understand that those two types of function (validity of beliefs vs. social coordination) are rather independent of each other. Shared beliefs can be completely false but work quite well as culture common ground and group 'glue'. This function can be largely independent of the truth of what is mutually believed [21].

In conclusion, it seems clear that for a belief (which is the mental form of many memes) to be accepted, preserved, and transmitted by an agent, its impact within the belief structure of that mind is crucial. More precisely its credibility, based on the reliability and the number of sources, and on the internal plausibility, its epistemic importance (explanatory impact and integration), its likeability... and even its moral appropriateness, but also the mere memorization [23] and retrieval, play a crucial role. Different motives and plans push individual to share beliefs by passing them or adopting them just in order to share them.

7. A more general and sophisticated model: Two crucial 'decisions' and their emergent effects

Let us now look at meme adoption and transmission more in depth, by expanding our simple model (Figure 1) in terms of the Agent's *decisions* and relatively not only to observed behaviors but to meme transmission via actual *communication*. We have in fact to deal not only with observation but also with explicit messages [12] aimed at inducing the addressee to believe or to do something. In such more analytic view of the mental processes involved in meme transmission, we observe that:

the so called 'contagion' can be the result of *decision* processes (to believe or not; to adopt or not), and

the so called spreading can be the result of another possible *decision*: to pass or not to pass such a meme to others.

The agent is very far from being a *passive 'vehicle' of memes*; it can actively decide about receiving them and passing them.

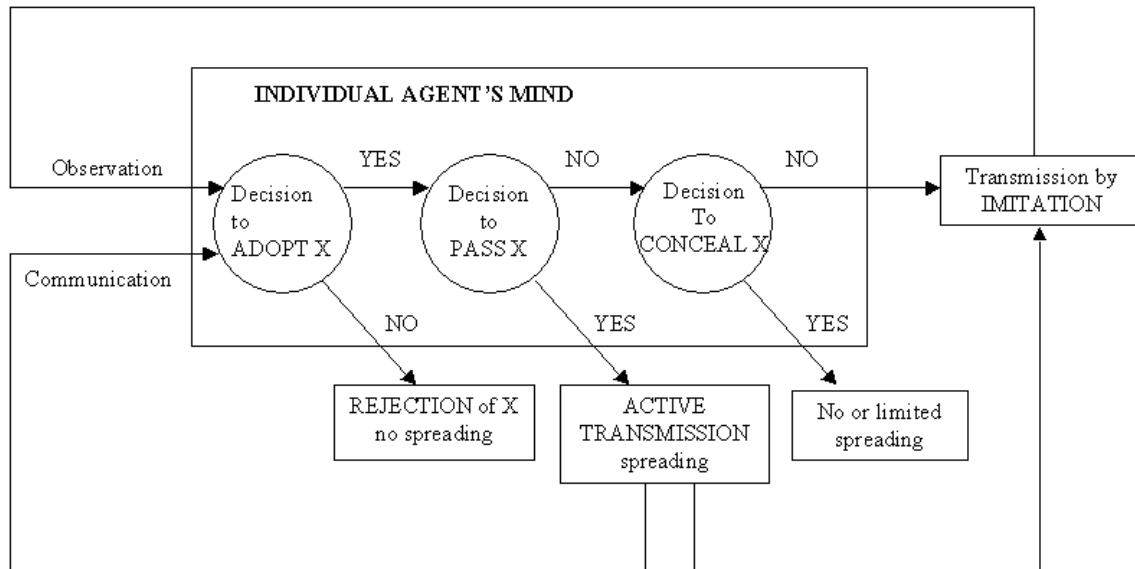

Figure. 4

As we can see in this simplified schema of the agent's decision process -relative to candidate memes coming either from the observation of a possible Model or from the communication by a source- the agent (on the basis of its interpretation and motives, see Figure 1) has to decide

i) whether to adopt or not such a belief, behavior, or method/tool; in case of rejection there will be no spreading of such a meme - at least through this agent; in case of adoption the agent faces another decision (based on other kinds of reasons):

ii) whether to pass this meme to other agents or not; if the agent intends to transmit this information it will either explicitly communicate (information, prescription, advice, instruction) or make the others observe its own behavior ('behavioral communication' - [12]); while, the decision of not actively transmitting its knowledge means:

iii) either to actively try to conceal and hid it; or

iv) not to care about its diffusion and just let the others observe or not and imitate or not it (the same hold for a *lack* of decision of transmitting or not).

It is important to remark -as we did at the end of section 1.3 - that the spreading of a behavior or

of an idea is not necessarily intentional (decided by the agent M); there is some room in this model for forms of 'imitation' (meme adoption) not due to M's decision to spread it around. But there is also room for intentional spreading or suppression [note 16].

7.1 Macro-layer effects

If we looked at the spreading of a given behavior (or belief) at the macro (population) layer, we would observe different 'contagion' or propagation properties of those socio-cognitive micro-mechanisms. The speed and the direction of propagation would be different for each mechanism; and also relative to specific memes (in fact, different memes may use different mechanisms and meet different cognitive and motivational problems because of the specific beliefs, norms and motives of the candidate vehicle). Some area of the population could be quite 'viscous' in propagating a given meme, while another could be completely resistant to any invasion. For example, an active role of the individuals in the propaganda of a given meme and in influencing the others predicts (*ceteris paribus*) a higher spreading speed than the mere casual observation of the behavior where the Model is passive and indifferent and adoption is a mere individual choice. The same holds for prescribed behaviors and values diffused either through the decentralized and diffuse social control or through enforcing authorities (or both). Analogously, social monitoring and moral or legal prohibition of given behaviors will make much more *stable* (difficult to change) the customs of a given group and more *uniform* (less variance within the population, and more intolerant culture).

Different socio-cognitive micro-mechanisms make different predictions as for their emergent effects in meme propagation

Emergent memetic macro-layer properties are the output of the specific socio-cognitive processing of the memes at the micro-layer.

8. Concluding remarks

Knowledge (either practical, deontic or factual) is not acquired and transmitted by mere 'contagion'. It is shared on the basis of adoption and passing, or not shared on the basis of rejection or not passing. Two crucial *decisions*.

It is important to model the various cognitive mechanisms and motives for *adopting* a trait (like the ones examined in section 2., 3. and 4.) or a belief (section 6.). However, not less important is modeling evaluations and motives supporting the decision to share or not a given piece of knowledge. It will also be quite important, for the theory of cultural construction and diffusion, to analyze when and why sharing knowledge or diffusing a behavior is a conscious goal of the agent or is just an unintended functional effect of its behavior [8; 11], and which are the different effects of intentional vs. merely functional diffusion. I just gave some example of those mechanisms, some preliminary model of them and some hint about their different conditions and effects, and different predictions that they allow at the macro-layer. Those models should be much better specified, other mechanisms should be modeled, and in particular their combined and massive effects should be experimentally studied using Multi-Agent based simulation approaches [31]. I just hope to have insinuated the suspicion that to adequately study the social

dynamics and evolution of memes we need somewhat complex 'cognitive' agents and the modeling of meme mental processing [17; 10].

Minds are not the *only* selection environment: the fire of the Alexandria library selected out billions of memes -ideas- that they intended to transmit to us. However, minds are the most relevant selective environment for memes, and for understanding cultural evolution it is necessary to identify (and simulate) the cognitive principles of the success or selection of memes *within minds*.

Memetics can only be cognitive, otherwise it is contradictory and non explanatory [note 17], but - of course - it should not be only cognitive.

Notes

1. On the notion of 'meme' and on the current debate about its nature and spreading mechanisms, see for example, [19; 4; 1; 20; 28; 29; 37]. For a different and quite interesting approach -that I will not explicitly discuss here- see Sperber [35].
2. Consider for example the spontaneous and unconscious mimic of phonemic, prosodic, and also lexical and grammatical features that we experience while visiting or living in a new linguistic environment, in particular when we are in contact with a dialect close to our own dialect. This is usually a non deliberated but merely automatic mimetic activity, and for sure it is a very relevant mechanism for the spreading and uniformity of linguistic rules and behaviors. Notice that it is based on some cybernetic purposive device (we adapt to a model and adjust on the basis of a match or mismatch) or at least on some 'anticipatory classifier' driven and reinforced by an expectation. For sure we do not evaluate any technical advantage of such (subjective) 'innovation', nor we do so because we have the explicit intention "to be like them; one of them"; this goal is completely implicit in some rule-based system or procedure.
3. For example to its "causal attribution" of the event; for example to and within the activated schemata, frames, or scripts [33].
4. This distinction -very important from a cognitive point of view- is also in Hedstrom's taxonomy [27]: do I repeat/imitate for imitating or for other purposes?
5. For a nice example of different interpretations of the same behavior -with different consequences on spreading- see also [17].
6. To be read as "A Believes that M uses x for the goal p".
7. To be read as "A Believes that M has the goal p" and "A Believes that x is good/useful for p".
8. To be read as "A believes that the new observed/known solution is better than any other solution he knows, for p". Notice that the individual also prefers not searching for a better solution; he believes that either he is not able or that an additional search is too costly. Consider

also that, when one of the motives is curiosity or the novelty is a value, a given solution can be better just because it is new -and until is new.

9. In this work, arguments and distinctions are very good, but the very definition of “rational imitation” is rather unsatisfactory.

10. They follow the authority for one of these reasons: her/his ideas are the true ones, the successful ones, the intelligent ones (competence, prestige in technical (section 2.) or in belief (section 6.) innovation and transmission); s/he is a distinguished person and being like her/him means being accepted by the group or being a distinguished person (section 4.).

11. It is clear that this overlaps with the normative mechanisms, because these are “prescriptions” by group X to belong to X. But the two mechanisms do not completely overlap, since there might be forms of normative adoption which do not concern identity and membership, and forms of adoption for identity recognition or membership about non-normative features.

12. Another very nice example of this goal of “being like them; being recognized as one of them” (intentional imitation), but for completely different reasons and motives, is camouflage. Consider a spy who does not like to be recognized and identified as a foreigner. He will possibly dress and behave like the local population in order not to be noticed. Of course here we have a faked assimilation and adoption of those traits, not a real memetic or cultural propagation. Notice that this kind of imitation-*mimesis* can occur for defensive reasons (ex. in shy and shameful people) or for aggressive reasons (ex. in the spy), like in animals.

13. This crucial goal can also have an independent (and even individual) origin. If I do not want to belong to a given class or group I’m supposed or expected to belong to, I have such a goal not as a consequence of being in another incompatible class or group, but perhaps as a premise of being part or looking for a different identity.

14. Otherwise it would be better to assume as a principle: *Believe something if you do not have reasons for rejecting it.*

15. We cannot prevent ourselves from believing in a source, unless we suspect that there is "something wrong" in it. [7]. In order to reject the information of a source (even of a social one) we must believe that there is "something wrong" in that source.

16. Consider that the notion of ‘decision’ can be interpreted in more or less ‘deliberated’ and conscious way (section 1.1).

17. Tomasello’s book has a rather Vygotskian title: “The cultural origin of human cognition”. I like this perspective; however, the other way around is not less important. I mean; the cognitive origin of human culture!

Acknowledgments

Abstract

This paper attempts to illustrate the importance of a coherent behavioral interpretation in applying evolutionary algorithms like Genetic Algorithms and Genetic Programming to the modeling of social processes. It summarizes and draws out the implications of the Neo-Darwinian Synthesis for processes of social evolution and then discusses the extent to which evolutionary algorithms capture the aspects of biological evolution which are relevant to social processes. The paper uses several recent papers in the field as case studies, discussing more and less successful uses of evolutionary algorithms in social science. The key aspects of evolution discussed in the paper are that it is dependent on relative rather than absolute fitness, it does not require global knowledge or a system level teleology, it avoids the credit assignment problem, it does not exclude Lamarckian inheritance and it is both progressive and open ended.

Keywords:

evolutionary algorithms, genetic programming, social evolution, selectionist paradigm

Introduction

1.1

There is now a significant body of work in social science (though predominantly in economics) which can legitimately be referred to as evolutionary. This paper focuses on simulations which use various kinds of evolutionary algorithms^[1] to represent social and particularly economic processes. There are now enough simulations of this kind that an "existence proof" has clearly been provided. It may now be appropriate to step back a little and try to provide a more general rationale for models of this kind. That is the object of this paper. An attempt to find a coherent interpretation for evolutionary modeling serves three purposes. The first is self evident. It is easier to pursue a research program that has been set in some sort of order, albeit provisional and descriptive. The second is that evolutionary models have so far been carelessly criticized or ignored by orthodox economists and other social scientists.^[2] Many of the traditional criticisms rest on misinterpretations or take advantage of ambiguities in the interpretations used by researchers in the field. A coherent interpretation may also serve to improve the quality of subsequent debate. Finally, the process of building an interpretation reveals weak spots in the

current simulations and may suggest both immediate solutions and areas for further long term research.

1.2

The second section of the paper describes the evolutionary process in biology as it is typically represented by social scientists. We also draw out some of the implications of evolution that are relevant to what follows. The third section summarizes how these evolutionary ideas have been implemented in evolutionary algorithms of various kinds. The fourth section summarizes the "standard" interpretation of evolutionary simulations which has emerged and the way in which it relates to concepts like procedural rationality in economics. The fifth section focuses on a number of specific simulations, including our own work in progress, to refine this interpretation, pointing out its weaknesses and suggesting areas for further development. The sixth section concludes.

1.3

A synthetic paper of this kind is inevitably both derivative and speculative. I have provided a quantity of references and footnotes that would normally be excessive in the hope of pre-empting some of the "traditional" criticisms. My goal is not to lay claim to very many of the basic ideas presented in this paper, only to putting them into a logical order and providing an extended critique which I hope will be provocative but helpful. (In addition to criticisms of prevailing approaches, I have also provided descriptions of alternatives wherever possible.) I am also trying to address two audiences and provide something of interest to both. The first audience are those who have not given too much thought to the possibilities of evolutionary models and the second are those who actually work in the field. Obviously keeping both groups interested is a rather delicate balancing act. This raises a final tension in my objectives, between current practice and future possibility. Although the paper focuses on examples from economics, the importance of a correct interpretation of evolution applies to modeling involving evolutionary algorithms in *all* the social sciences, even though in some it is barely used at present. Runciman (1998) discusses the profound lack of enthusiasm for evolutionary models in sociology and this attitude has proved so pervasive that no simulations (at least analogous to those described here) yet appear to exist in the discipline. Rather than providing a review (an exhaustive but essentially reactive description of existing work), this paper attempts to develop a thesis with appropriate illustrations. The thesis is that the coherent interpretation of social evolution (what Runciman calls the "selectionist paradigm") is both possible and desirable. For this purpose, the most appropriate illustrations are the best developed models which currently exist. However, it is hoped that in future models based on a coherent interpretation will increasingly be developed and applied in new areas. This paper is intended as a small contribution to that larger project.

Evolutionary Biology and Evolutionary Models

2.1

This section defines social evolutionary processes, summarises the mechanisms of evolutionary biology as they are typically used by social scientists and draws out their implications.

The Meaning of "Evolutionary" In Social Science

2.2

The term "evolutionary" has been much misused and reviled in social science. Four major interpretations can be distinguished. Firstly, there are Social Darwinist theories (Hofstadter 1955, Jones 1980), which are also associated with the ideas of eugenics. Such theories were often mere political rhetoric, and were so imprecise they could easily be used to support or oppose the same policy. They now have little more than historical interest since they made no attempt to justify the analogies they proposed between individuals, states or firms and individuals or species in biology.^[3] In some cases, they appear to have been based on misunderstandings of what Darwin and subsequent evolutionary biologists actually said. Secondly, there are Sociobiological theories (Wilson 1975, Wilson 1978). These attempt to explain certain behaviors, traditionally regarded as social, in genetic terms. Theories of this kind are not ignored here because they are of poor quality, but because it is generally assumed that there is a realm of distinctively social behavior. Sociobiology may alter the size of this realm and force us to reconsider the explanations of certain behaviors at the margin, but it does not seem likely that it will swallow up the core of social science. Thirdly, there are theories which simply deal with change, including change in the very long term. Institutional economics has often been described as evolutionary in this sense (Hodgson *et al.* 1994). Our reasons for disregarding theories of this kind are more tentative. As with Social Darwinism, *some* of these theories use evolution in a sense that is more rhetorical than substantial (Petr 1982). They stress the (subjectively) functional nature of certain institutions and practices without saying much about how functionality might arise or how functional and non functional practices might be distinguished within a scientific framework. This is not to say that institutional economics has not made an extremely valuable contribution to unorthodox economics, nor that some models originating in the field are not evolutionary in the sense defined in this paper. The main reason for excluding most models of this kind is semantic and pragmatic. Institutional, historical or dynamic economics are perfectly appropriate terms to describe most of these models. By contrast, the models discussed in this paper would be almost impossible to describe in any other way. The final sense of evolutionary, and the one we shall use in this paper, refers to models or simulations which propose a detailed and coherent analogy between a biological evolutionary process and a social process.^[4] The biological evolutionary process chosen is usually that referred to as the Neo-Darwinian Synthesis (Darwin 1968, Fisher 1930, Ridley 1985, Edey and Johanson 1989) which combines Darwin's theory of natural selection with Mendelian genetics.

The Neo-Darwinian Synthesis and Its Implications

2.3

For the purposes of this paper, this evolutionary theory can be summarized quite briefly. The objects of the theory are individual living creatures, which each consist of a *genotype* (a certain arrangement of genes) and a *phenotype* (the rest of the physical body which was "constructed" by that genotype during the process of gestation.) This construction process involves the genes "encoding" the synthesis of the enzymes and other molecules required to orchestrate the growth

of an individual from a single cell to the point of birth. The environment, which consists of other individuals and physical structures, *selectively retains* individuals depending on the "performance" of their phenotypes.^[5] This performance involves persisting for long enough to reproduce, thus perpetuating the successful genotype. Two other important mechanisms take place during the reproductive process.^[6] In sexual reproduction, there is *genetic mixing*, the genes of the offspring contains some of the genes of *both* parents. In addition, the normal duplication of genes results in *mutation* through "copying errors", though this mutation can also result from external processes such as radiation. The functions of these two processes can be seen as the *generation* of novel combinations of genetic material (that may persist better in the environment than those which currently exist) and the *maintenance* of novelty. (We can envisage a situation in which, with a stable environment, genetic convergence will result. Mutation ensures that there is always a minimum of genetic diversity so that a subsequent change in the environment does not immediately result in the extinction of entire populations.)

2.4

For the discussion that follows, this process has several important and interdependent implications:

Evolutionary fitness is based on relative and not absolute success. There is no requirement for an "invisible hand" or any global knowledge to exist within the system. Nor is there any requirement for a "minimum standard" of performance before the evolutionary process can begin. Each individual interacts only with other individuals (and physical processes) and persists or ceases accordingly.^[7]

Evolution avoids the credit assignment problem. Individuals persist or cease on the basis of all their strengths and weaknesses taken together. It is not necessary for them to be capable of making attributions about the particular causes of success or failure.^[8]

Evolution neither requires nor implies an external teleology. Although individuals may have goals and drives, themselves evolved as responses to the environment, the system as a whole does not have a particular principle for selective retention. (This follows from the local nature of the evolutionary process. There is nothing for such a principle to inhere in.) In not requiring a teleology, evolution avoids an infinite regress of explanation and is self-consistent. However little we know about the actual structure of the first organisms, there is no point at which we are theoretically obliged to postulate a conceptual discontinuity in the evolutionary process.

Evolution is an open ended process in two senses. Because the role of genes is to encode chemical processes, rather than directly "construct" a phenotype by a fixed mechanism, a completely new sequence of genes can result in a completely new enzyme with previously unknown effects. Similarly, at a higher level of description, the phenotypic abilities that individuals have are not fixed: a stick can be used as a digging tool or a club and neither use is strictly determined by the structure of the arm or hand.

Evolution is progressive. This is not meant in a teleological sense, but it follows from open endedness and relative success. Initially, organisms would simply have come into existence and

ceased again. If one was able to make copies of itself (Dawkins 1989), then that would be the only one to persist beyond the life span of a single individual. Once persistence was ensured, with all persisting organisms being copies of the original, then properties such as diversity might have developed additional persistence value. Once diversity existed, then genetic mixing could have persistence value and so on.^[9]

Evolution does not exclude Lamarckian inheritance. It appears the Lamarckian inheritance - inter-generational genotypic transmission of phenotypic characteristics acquired during a single lifetime^[10] - has not evolved in biological systems except for some fiercely contested cases among the simplest organisms (McDougall 1927). It is also fairly easy to see why this might be. There is simply no mechanism by which additional arm muscles might be "re-encoded" back into the genes, because they are not directly encoded there in the first place.^[11] All that is encoded is the synthesis of enzymes and other chemicals that will, taken together, result in a particular set of muscles and other bodily features but *only through a dynamic process of construction*. The completed body does not retain any representation of this construction process, so it cannot be "reverse engineered". However, this is a contingent fact about genes. There is nothing conceptually incoherent about Lamarckian inheritance as part of an evolutionary framework. Indeed the existence of cultural transmission suggests that if the material of the "genotype" is human language, rather than genes, Lamarckian inheritance has indeed evolved and may now dominate genetic inheritance (Moravec 1989).

2.5

It is clear that these implications have considerable appeal for unorthodox economics and address serious problems with the orthodox view. The absence of system level teleology and global knowledge is appropriate for emergent phenomena like markets. Absolute success measures are inappropriate^[12] when agents are reflexive and operating in environments where their actions affect the choices available to others. (It is now becoming clear that these conditions obtain in almost all social processes of any interest.) With the addition of Lamarckian inheritance, evolution is neither incompatible with rational (directed) behavior nor with agents pursuing individual or collective goals.^[13] Finally, from the institutional perspective, it is encouraging that we can see the current state of social processes as a conceptually smooth progression right back to the most basic forms of social organization.^[14] Economics has often been accused of "naturalizing" and rendering ahistorical both the attitudes of the affluent middle class and the economic arrangements of late capitalism. By emphasizing process, as institutional economics does for example, the evolutionary approach opposes this tendency. In addition to these direct implications, the evolutionary approach also has potentially appealing rhetorical implications. It is fundamentally pluralistic and dynamic without being teleological. It stresses the descriptive and provisional nature of our understanding and places the understanding of the social scientist in a non privileged position *within* the evolutionary process. Finally, while it does not exclude deliberate or rational action, it situates this action in a context of profound environmental complexity and uncertainty. This context does not arise mysteriously, but naturally from the autonomy of actors and of the physical processes in the environment.

2.6

Furthermore, in challenging some of the assumptions of orthodox economics in a constructive way, the evolutionary approach moves it somewhat nearer to the perspectives of the other social sciences. Although sociology, economics and psychology will inevitably continue to differ in their views on the relative importance of social and individual factors, conscious and unconscious processes, rationality and impulse, decision and influence, it is much easier to integrate these insights within a broadly cognitivist framework which views agents (and social scientists) as having limited, diverse and provisional models of the world. It is in part the extremely strong (and occasionally dogmatic) assumptions of individualism, extreme rationality and a positivist treatment of quantitative and strictly behavioral data that have (perhaps unfairly) become identified with economics and effectively separated it from the other social sciences.

2.7

In the next section, we move away from biology to a discussion of the way that evolutionary ideas from biology have been used in the development of evolutionary algorithms.

Evolutionary Algorithms

3.1

In this section we will focus on three representative kinds of evolutionary algorithms: Genetic Algorithms (Holland 1975, Holland 1992, Goldberg 1989), Genetic Programming (Koza 1992a, Koza 1994) and Classifier Systems (Holland 1975, Holland 1992, Holland *et al.* 1986, Goldberg 1989).^[15] In each case, the algorithm involves generating an initial population of individuals and then operating on that population iteratively so that over time the "quality" of the individuals persisting in the population tends to increase. The operations involved and the structure of the individuals in the population are what make the techniques different. Genetic Algorithms (GA) and Genetic Programming (GP) differ mainly in the structure of individuals, while Classifier Systems (CS) not only have a different individual structure from the other two techniques, but different operations too. In the same way that we have abstracted from the intricacies of biological evolution, we shall try to abstract from the implementation details of evolutionary algorithms. Not only are there many different kinds of evolutionary algorithms, but there are many different variants of each kind and many parameter values that may be controlled in each variant. We shall raise these issues only when necessary. For a more detailed overview, we refer the reader to Goldberg (1989), Koza (1992a) and the references in Nissen (1993).

Genetic Algorithms

3.2

In a GA, each individual is represented as a string of numbers which are often binary. These individuals are typically generated randomly.^[16] The three main operators applied to the population are *reproduction*, whereby more copies are made probabilistically of fitter individuals, *crossover*, whereby two individuals are chosen probabilistically on the basis of

fitness, "cut" at the same point and the tails of the strings "flipped", and *mutation*, whereby a single position in an individual is changed randomly to another syntactically acceptable value. (If the numbers in the string are binary for example, then 1 is flipped to 0 and vice versa.) Fitness is defined by a function, called the *fitness function*, which maps all syntactically acceptable strings into a corresponding fitness. Crossover corresponds to one process of genetic mixing in sexual reproduction, while mutation serves the same diversity maintenance function as it does in biological evolution. While the technicalities are rather complex, it is intuitively clear why the population fitness gradually improves. Reproduction results in a higher proportion of fitter individuals in the population. It is these that probabilistically form the subjects for subsequent crossover and mutation. Unfit individuals which result will not persist, but any that are better than the current individuals will in turn come to dominate the population. (This is where relative performance is important.) Even if the initial population is randomly generated, there will always be one individual that performs the tiniest bit better than the others and this will be enough to start the evolutionary process off.

3.3

While the similarity between a GA and biological evolution is fairly clear, there are at least two important differences even at a conceptual level. Firstly, the existence of a fitness function provides both an "invisible hand" and a teleology for the system. The fitness function allows the fitnesses of all individuals in the population to be compared and both proportionate and rank based fitness functions rely on this "global" knowledge. Whatever properties of an individual the fitness function indicates as "desirable" are the properties that will become more prevalent in the population. It is this which provides the teleology for the system. Secondly, no distinction is made between the genotype and phenotype of the individual. The fitness function is able to evaluate an individual directly on a genotypic basis, rather than through some phenotype to which that genotype gives rise.

3.4

Both of these differences can be explained by the "standard interpretation" of the GA as an *instrumental* function optimizer.^[17] If the point of a GA is to serve as a tool allowing the programmer to find the optimal value of some fixed function, then global knowledge and a designed fitness function are both appropriate and necessary to that task. Rather than modeling natural selection, the programmer is attempting husbandry, incorporating an exogenous fitness function into the program in the same way that animal breeders measure their success by the amount of extra meat on a new strain of cow relative to the current herd.^[18] However, for the purposes of this paper, we are interested in the extent to which evolutionary algorithms are capable of serving as *descriptive* models of social processes. (In such cases, the assumptions of global knowledge and a shared teleology are probably not appropriate.) In the same way that we have described evolutionary models in general as those which specify a coherent analogy with biological evolution, so we can envisage simulations based on coherent analogies with evolutionary *algorithms*. It is to these analogies we turn in section four, but for now, we continue with the technical description of evolutionary algorithms.

Genetic Programming

3.5

GP also typically makes use of the operators of reproduction, crossover and mutation. However, the individuals in the population are *programs* in some (simplified) programming language. A commonly used language consists of the set of possible trees for a specified set of operators (internal nodes) and terminals (leaf nodes).^[19] For example, the set of operators could be $\{+ | - | * | / \}$ and the set of terminals $\{0 | 1\}$. This language would produce a set of trees involving simple mathematical expressions of arbitrary depth.

3.6

Again, it is clear that this technique has a simple instrumental interpretation and GP has indeed been used for pattern induction and function estimation (Koza 1992b). However, there has also been a significant increase in representational richness in at least two senses that prove to be relevant for descriptive models of social processes. Firstly, the tree representation allows for individuals of arbitrary depth.^[20] Secondly, the interpretation of a GP tree is decomposable in a way that a GA string is not. If the operators are chosen to have "obvious" meanings, so that + refers to the addition operation, for example, then GP trees can be parsed by a human almost as easily as by a computer. Decomposability is demonstrated by the fact that an individual can be presented with a syntactically correct GP tree fragment like $(+ (+ 3 5) \dots)$ and parse it to $(+ 8 \dots)$. By contrast a GA string fragment $(\dots 0 1 0 \dots)$ makes no sense unless one knows its exact position in the string and even then it is necessary to refer to the coding of the fitness function.^[21] This decomposability is not purely a matter of comprehensibility, it also corresponds to a specific problem with the GA as an instrumental optimizer. Although there is no technical reason why a GA string should not encode an arbitrarily complex structure, the more complex it gets in practice, the greater the danger that optimization will be dramatically impaired by the unequal importance of different string positions in producing fit solutions. Instead of truly parallel search, the GA will tend to optimize the most important positions first and then progressively optimize the less important ones. (This is the problem of *epistasis* Goldberg 1989: 46-48).^[22]

3.7

Despite this increase in representational richness, GP techniques are still used predominantly in an instrumental way (Koza 1992a). They are set up to assume global knowledge, no phenotype/genotype distinction and the exogenous teleology of the fitness function. However, the richer representation possible in Genetic Programming has drawn attention to the fact that even for instrumental applications:

It might be appropriate to evaluate the fitness of individuals on the basis of repeated program outcomes and that these outcomes need not be separable;

Terminals and operators could just as easily be interpreted as *actions* in a simulated environment.

3.8

An obvious example of the former is evolving a program to generate random numbers (Koza 1991). In this case, the fitness must measure the statistical properties of *sequences* of numbers and can do nothing with single instances. As an example of the latter, consider evolving a program to serve as a controller allowing a robot to perform a simple task like finding litter and picking it up (Koza 1992c). In this case, the "output" of the GP can correspond to an *action* in a simulated environment like "Turn Left" or "Pick Up" rather than simply generating a number. (For instrumental applications, the programmer can *interpret* a number as indicating an action, but for descriptive simulations avoiding an external teleology, it is required that the interpretation be encoded in the program itself.^[23]) In addition, we are now making a concrete distinction between genotype and phenotype. The program is the genotype, but the execution process and actual outcome of executing the program in the simulated (or real)^[24] world involves the phenotype.

Trivially, if the indicated action is "Move Forward" but the robot is facing a wall, the phenotypic outcome will be a dented robot! Although both of these applications are still instrumental, it is much shorter step, at least in the latter case, from asking how we might get a robot to optimize its performance of certain tasks given its abilities, to asking what behavior we might expect to observe in an agent with certain abilities, when it is exposed not to teleological selection, but to selection by the physical environment, by other agents, or a combination of the two.^[25] We consider various answers to this question in section five.^[26]

Classifier Systems

3.9

The final class of evolutionary algorithms we will discuss in this section are Classifier Systems (CS).^[27] In a CS, the individuals consist of IF ... THEN ... rules (condition-action pairs).^[28] The architecture of the CS is rather more complicated than those of the GA and GP. It begins when suitably encoded input from the environment is added to the "message list" of the CS. This input may satisfy the conditional part of one or more rules in the "rule base". Each rule has an associated strength, which reflects its past success at contributing to the generation of "appropriate" output. Eligible rules compete in an "activation auction", a probabilistic process in which fitter rules are better able to make high "bids" for activation on the basis of past performance. Once it has been established which rules are to be activated, they are copied to the message list and the combination of inputs and rules is "executed". (The combination of inputs and rules may generate outputs to the message list which in turn make new rules eligible.) As well as outputs to the message list, some rules will presumably generate outputs to the environment and these are also carried out. After this, the message list is purged. The outputs to the environment generate environmental feedback, which is used to alter the weights on rules.^[29] Finally, a GA is used from time to time to weed out lightweight rules in the rule base and generate new ones probabilistically from those with greatest weights.

3.10

Despite its apparent complexity, the CS actually functions in a rather similar way to the GA and GP. The population of the rule base should gradually improve in quality as time passes. The activation auction corresponds to the probabilistic application of genetic operators like crossover and reproduction to determine which individuals are actually "used" for tasks. The weights on rules can be seen as an alternative to duplicating fitter rules through reproduction in the GA or GP population. (One rule with a weight of 1 and four with weights of 0 are equivalent to a population of any size consisting only of multiple copies of the first rule. The analogy is not perfect. In the latter case, the rule diversity has really been lost, while in the former case the rules are still "available" if the weights should change. We will return to this point.) The "environment" can either be some instrumental task like summarizing a set of cases, or a descriptive simulation of a real environment. As with the GP, the existence of rules which generate outputs to the message list as well as the environment allows for output behaviors of arbitrary complexity. The most important difference between the CS and GA/GP is that the CS explicitly produces strategies that consist of *sets* of rules which deal with a particular environment collectively. By contrast, even though GA and GP produce diverse populations, the idea is that only the fittest individual in that population will be "used" at any one time.^[30] This difference supports descriptive uses of CS and raises questions about the flexibility of the responses of simple GA and GP to systematic environmental variation. Although a single program in a GP *can* cover all the cases in an arbitrary rule base, the resulting program will be very large, unwieldy and perhaps difficult to interpret.^[31] In addition, the majority of the program will be redundant most of the time.

We will return to this issue in section five.

3.11

To sum up, it can be seen that even in their most simplified forms, evolutionary algorithms are a creditable abstraction of the biological evolutionary process. However, some caution has to be exercised in using them as models of social processes. In particular, their origin as instrumental optimization techniques may be incompatible with desirable features of biological evolution like the absence of global knowledge and external teleology. In sections four and five of this paper we will focus on a number of specific simulations to see what they reveal about the potential and limitations of evolutionary algorithms as representations of *social* processes.

The "Standard Interpretation" Of Evolutionary Simulations

4.1

Although the simulations differ in detail, it is possible to present a "standard interpretation" of genuine evolutionary simulations which forms the basis for discussion in this section. (Section five attempts to generalize and develop this interpretation.) The standard interpretation draws on several different strands of thought from unorthodox economics. Two of these will be addressed now and others will emerge as the discussion proceeds. As has already been remarked, many of the insights which follow are taken for granted in sociology and psychology.

4.2

Probably the most important ideas underpinning these simulations are that rationality is genuinely bounded and procedural (Simon 1972, Simon 1976, Simon 1978, Simon 1981). Unfortunately, until relatively recently, the idea of bounded rationality seems to have been reincorporated into orthodox theory as a generalization of standard economic rationality rather than an ontologically different theory of human decision.^[32] For example, the observation that decision making is time consuming and cognitively difficult formed the basis for models in which agents were supposed to optimize their allocation of time to the decision process (Winston 1987). The same logic was used to transform the observation that individuals and organizations tend to use "rules of thumb" into an optimizing theory (Baumol and Quandt 1964). Simon himself is responsible for two of the most damaging criticisms of this approach.^[33] In the first place, it involves an infinite regress of explanation. Does the agent include time spent deliberating about how long to deliberate as part of the calculations for the deliberation? Is the rule of thumb chosen using a rule of thumb? If so, how is *that* rule of thumb chosen? In each case, what appears *prima facie* to be an explanation actually involves postponing any real grounding for the theory? Lest it be thought that this is no more than the general problem of reductionist science, Simon further points out that the regress is not leading to explanations of equal or increasing simplicity and power, which would be helpful,^[34] but to explanations of increasing difficulty, which is not. It is intuitive that the rule of thumb for *choosing* rules of thumb must be at least minimally more complex than the rules which it must choose between since it must be capable of not only "executing" those rules but evaluating them. A related point is that information requirements increase for each level of regress. If the rules of thumb contain any parameters which must be tuned for effective use, the rule of thumb for choosing must have *its* parameters tuned to take account of different values for the rules of thumb it is supposed to decide between.^[35]

4.3

The solution is obvious, but extremely different from the orthodox view. Instead of rationality consisting of a "disembodied observer" who is able to look down on mental states from whatever height is required to get the complete picture and act "rationally", to some extent, rationality *must* be "embedded" in the unfolding of those mental states to avoid an infinite regress. The metaphor of the observer is a useful one. The fact that a human observer is embedded in the world certainly does not preclude them having some choice over which direction to look in, though parts of any view will be obscured by trees, fog or whatever. The observer can also change their point of view by walking or going up in a balloon, for example, and this may clear some obscurities, though it will almost certainly introduce others. However, at the very least, any observer is typically prevented from observing the state of their own forehead! If a mirror is used, this observation is possible, but at the expense of any view of what is going on behind the mirror. This example is a purely heuristic one. It shows that any embedded system has at least one "blind spot" in addition to its obscurities, but says nothing about how big it is. The nature and scale of obscurities and blind spots in the mental process is an open question, but we can be almost certain that rational choice theory, which postulates no genuine blind spots at all, is incorrect. Furthermore, the existence of even the smallest blind spot changes the whole nature of the decision process, since any decision can no longer be absolutely known to be rational. This

difficulty is more serious than that of mere probabilistic risk because there can also be no knowledge of the degree of uncertainty induced by the blind spot, since its "size" and "scope" cannot be determined either.^[36]

4.4

The implication of this embeddedness is that at some level, as Simon argued, rationality can only consist of "unselfconsciously" following procedures. Two procedures can be compared, but they are compared by something that is itself a procedure and cannot be rationally justified beyond a certain point.^[37] (Wittgenstein 1953 makes the same point in his discussion of "language games".) One cannot step outside the whole mental process and "straighten it out".^[38] At best, from any particular mental point of view, one can make comparisons and attempt to remove inconsistencies. (Always allowing that changing things to remove one local inconsistency may introduce another somewhere else.^[39])

4.5

This interpretation of bounded, embedded or procedural rationality strongly suggests a computational approach. Although a computer program can modify the state of its variables, and in some cases even its own code, at any point it must take the variables and state of the program as given when executing a particular instruction. Thus, in addition to the general advantages of computer simulation (Doran and Gilbert 1994, Chattoe 1996), there is also a conceptual similarity between programs and mental processes.

4.6

A second related theme, which is suggested by the absence of rational justification for procedures, is that agent models of the world are something quite distinct from the world itself (Chattoe 1994, Moss and Edmonds 1994). Agents do not, as orthodox economics sometimes suggests, all have knowledge of the correct model of the world or even of the same model with divergent opinions about its parameters.^[40] It is only in the context of an evolutionary theory, which assumes diversity, that the enormity of this assumption becomes clear. Everyday experience overwhelmingly suggests that agents differ not only in their preferences, but in their calculative techniques, their views on achieving goals and so on. Situations where beliefs or goals based on anything other than direct perception are widely shared are not the norm, but a fascinating field for social research.

4.7

The analogy between this view of agency and the description of biological evolution in the second section is fairly clear. Actors, which may be individuals, families, social groups, firms or governments, can be viewed as having both a genotype, which consists of their more or less *persistent* mental processes and operating procedures, and a phenotype, which consists of all the other "physical" aspects of their functioning, including the impact which they can have on the environment. The genotype is distinct from the phenotype, but "constructs" it, since we assume that actors are intentional.^[41] Phenotypes, and through them genotypes, experience selective retention by the environment. In addition, the processes of genetic mixing and mutation also

have their analogues. Genetic mixing occurs during the process of learning by imitation and mutation can result either from incorrect copying of a genotype or random (undirected) experimentation. (These processes will be analyzed in more detail in section five.)

4.8

The implications of biological evolution sketched out in the second section are also congruent with this analogy. In the great majority of cases, "fitness" in social situations must be measured in relative and not absolute terms. The complexity of the environment (consisting of the autonomous and interacting behavior of diverse individuals as well as purely physical processes) means that credit assignment for particular modifications to the genotype is extremely hard to implement. This affects the type of learning and adaptation mechanisms we can expect to observe. The *ceteris paribus* requirement (to which orthodox economics often appeals) can seldom even be maintained in the genotype of a single individual. In particular, the refinement of cognitive models involves the acquisition and organization of new knowledge. This means that cognitive agents cannot easily "step into the same river twice" as far as their perception of the environment is concerned. This in turn means that agents will perform new actions, based on new inferences, and influence the environment in new ways, requiring other agents to modify their practices accordingly. This gives a "direction" to the social process and removes the costless reversibility which is typically assumed in orthodox economic models.^[42]

4.9

This leads on to the fact that social processes are also both open ended and progressive. Simple arrangements for buying and selling, fighting or building settlements gradually diversify and increase in complexity as knowledge is created and organized by agents. Over time, genuinely new products, institutions and technologies are incorporated into the social process.^[43] Open endedness reminds us that economic systems, like biological ones, do not imply or require an external teleology, even though it is almost a matter of definition that autonomous agents should have *internal* goals. This point needs some clarification, since in some contexts, particularly the interaction of firms in a market, the absence of an external teleology is somewhat obscured by "market rhetoric".^[44] It is certainly true that there are many laws and customs, more or less well observed, designed to regulate the function of markets and other social institutions, but not that they reflect any coherent or agreed plan to support "efficiency" or indeed any unitary goal, nor that they can be expected to ensure any particular social behavior such as profit maximization in competitive firms.^[45] Indeed, the structure of institutions like the market often reflects some of the interests of the very "players" who are supposed to be "regulated" by them.^[46] Although firms will adapt to the structure of the market place, this structure is not coherent, binding or permanent enough to constitute a teleology, any more than it would be valuable to talk about other individuals constituting an external teleology.^[47]

4.10

Finally, although we have so far focused on a pure evolutionary process, we are not obliged to exclude various mechanisms of Lamarckian inheritance in social systems, because it is much easier to see how phenotypic effects can be re-encoded into the genotype when the material of

the genotype is everyday language rather than DNA. This process of re-encoding is precisely what we mean by directed or "rational" adaptation, as opposed to evolutionary adoption. It is important to stress both that evolutionary models are *not* intended to exclude rational or deliberate behavior and that the evolutionary view of bounded rationality is actually straightforwardly compatible with many forms of learning. Many critics of evolutionary models (Penrose 1952) accuse them of asserting that human behavior is either random or genetically determined. This is simply incorrect. These same critics also fail to recognize that the technical reasons why Lamarckian inheritance cannot occur in biological systems are not necessarily binding on social systems. Finally, while it is true that evolutionary models can easily incorporate learning as Lamarckian inheritance, attempts to incorporate evolutionary behavior into "rational" models have so far been much less successful. Two of these attempts, the GA models of Arifovic and the use of replicator dynamics in game theory, will be discussed subsequently. On the basis of the foregoing discussion, two of the most important general questions raised by evolutionary models are:

How much rationality is actually required for the level of organization we observe in social processes?

How can social evolutionary processes *interact* with rational decision?

4.11

On the basis of the evolutionary models discussed in this paper, the answer to the first question is considerably less than orthodox economics has previously suggested. The answer to the second question is much less clear cut and one of the reasons for attempting a coherent interpretation of evolutionary models is precisely to make the boundaries between evolutionary adoption and rational adaptation clearer. (If economics is guilty of over-playing the role of deliberate action, then perhaps sociology and social psychology are guilty of under-playing it.) Before moving on to a detailed discussion of models in the next section, the last purpose of this section is to examine two interdependent aspects of the analogy between biological and economic systems that are traditionally regarded as problematic.

4.12

These aspects are the relationship between the measurement of individual "lifetimes" and the objects of evolutionary selection. For biological evolution, in the absence of Lamarckian inheritance, there is a unique relationship between a genotype and a corresponding phenotype. Once we allow Lamarckian inheritance, this is no longer true and a particular individual can no longer be identified with a fixed genotype. However, this does not, as Penrose suggests in the context of industrial evolution, raise any difficulty with the "identity" of firms, nor are we obliged to treat each change in the genotype as the creation of a "new" firm.^[48] Any such argument fails to understand the definition of Lamarckian inheritance. It is precisely a change in the genotype *during the lifetime of the individual*. One of the things that is often understated in evolutionary modeling is the empirical integrity of the objects of selection which typically form the basis for models. It is trivial that individuals display the properties of organisms: autonomy, internal structure, a well defined boundary and mechanisms of self-maintenance. However, these

properties are also very much in evidence in organizations and social groups of all kinds, and particularly in firms with actual or potential competitors. The boundary is maintained by the distinction between employees and others, the use of "non disclosure" agreements for departing employees, the importance of tacit knowledge and "on the job training" and by more intangible phenomena like "company pride". The combination of a correct interpretation of Lamarckian inheritance and the observed integrity of individuals and groups resolves the apparent difficulty. The objects of selection really are organizations and individuals and their lifetimes really are the periods for which they persist. This resolution does however raise a subsidiary issue, which is that very few social processes appear to take place over the real life span of groups or individuals.^[49] If this were actually so, then the role of evolutionary mechanisms would of necessity be considerably weakened. The answer is that although we have stressed Lamarckian inheritance as a way of fitting *directed* learning into an evolutionary framework, there is no conceptual reason why it shouldn't equally apply to the effects of undirected learning within the individual lifetime. All that remains is to distinguish more clearly what we mean by directed and undirected learning and that is a task postponed until later in the next section.

Focusing and Developing the Standard Interpretation

5.1

Ironically, but perhaps not surprisingly, two of the best known kinds of evolutionary models are the least satisfactory from the point of view of the foregoing discussion. This is because they attempt to reincorporate evolutionary ideas into an orthodox economic framework without due regard for their logical coherence.

How Not To Use Evolutionary Algorithms

5.2

The first set of models is GA based and has been developed by Arifovic and others (Arifovic 1990, Arifovic 1994, Arifovic 1995, Arifovic 1996, Arifovic and Eaton 1995, Bullard and Duffy 1994). In these models, pricing or other decisions are coded as GA strings which then undergo the usual operators of reproduction, crossover and mutation, along with an additional *election* operator which will be explained shortly. Arifovic (1990) draws attention to two different interpretations of the GA, which will be useful in what follows. The first could be called the *mental interpretation*, in which GA strings represent different possibilities in the mind of a single agent or organization. Under this interpretation, individuals carry out the operators on their own mental contents, using the fitness function to pick the string which actually generates an action in any particular period. The second is the *population interpretation*, which is the one that Arifovic favors and uses subsequently. Under this interpretation, each individual consists of a single string and the GA consists of a *population* of individuals. The first difficulty with these models is the criteria by which they should be judged. The behavioral interpretation provided is cursory and it appears that the objective of these models is to simply to obtain or "explain" convergence to the equilibria indicated by analytical models. In particular, Arifovic (1990) is quite specific about introducing the election operator to deal with what she describes as the "problem" of non-convergence.

5.3

For now, we will assume that Arifovic intends her model to be interpreted descriptively. The interpretation of crossover as learning by imitation and mutation as copying error or random experimentation are fairly straightforward. However, the absence of a genotype/phenotype distinction and the choice of crossover as the mixing operator have important implications. It appears that one agent can look directly into the head of another and perceive what it intends to do.^[50] Furthermore, crossover imposes a lot of "structure" on the imitation process, ensuring that it always produces new strings that are syntactically correct. Thus agents can not only read each other's minds, but do so with such clarity that they always imitate fully formed "concepts" despite the highly structured encoding of the GA string. (This structure may also cause the problems with mutation that lead to the introduction of the election operator. Mutation at some positions may have far more effect on the fitness of the string than at others. This is undesirable purely from the point of view of design.) The reproduction operator produces larger numbers of fitter strategies in the population. This operator can be interpreted in two ways, but both are problematic. The first is that the environment imposes the removal of less fit firms and, by implication, the increase in the population of fitter firms. However, while it is easy enough to see why unfit firms might be removed by bankruptcy, it is much harder to say what properties replacement firms would have, and in particular how they would be able to imitate the practices of only fitter firms. (The argument usually given is that new firms adopt market "best practice" but this assumption needs more support. In particular, if this option is available to new firms, why is it not open to current firms performing poorly?) Nothing is said about how the time scales implied by this interpretation can be reconciled with the speed of environmental change in real markets. The other possible interpretation is that reproduction represents imitation of the whole strategy of another firm on the basis of fitness. The two difficulties with this interpretation are firstly, that observing utility is even more implausible than observing intentions^[51] and even if we grant this as a possibility, secondly, there seems to be an strong implication of global knowledge to ensure that people imitate in proportion to the overall distribution of fitness. Another possibility is that firms could "learn" the fitness distribution in the market, but it is not clear that they could do this fast enough in a dynamic situation. (Both interpretations of the reproduction operator also suffer from the absence of a clear genotype/phenotype distinction, since it is not obvious whether we are talking about the success and failure of real firms or of the strategies adopted by those firms.)

5.4

The interpretation of the election operator is similarly ambiguous. This operator is applied to the process of crossover. Both the crossover products are assigned a *potential fitness*, an expectation of how they are likely to perform on the basis of their performance with past data. If the potential fitness of either crossover products exceeds the actual fitness of the "parents", then it will replace that parent in the population. Full crossover is far harder to justify than a "half crossover" (imitation) and without that, there will not be a pair of crossover products or parents. We *can* apply the same algorithm to the decision as to whether or not to incorporate an imitated section of string from another agent, but it is still not clear what it is about the organization of the environment that ensures that agents are presented with imitation opportunities in proportion to their fitness. (Again, a real phenotype might provide a solution, with firms tending to imitate

those displaying similar patterns of *outward* behavior or observable features like size and age. This is the approach taken in Chattoe and Gilbert 1997.) In fact, it seems that if agents are so well informed about fitness and the intentions of other agents, they should be able to decide for themselves whether or not to imitate, regardless of the state of the other firms they are presented with. Thus election is in danger of rendering reproduction redundant and turning the GA into a hill-climbing algorithm with all the attendant drawbacks such as non global convergence.

5.5

The other class of well known evolutionary models are those in game theory using the so called replicator dynamics.^[52] This is a rapidly expanding field (Weibull 1995, Vega-Redondo 1996) and there is not space to provide a detailed survey here. The main point that is relevant to the current discussion is that the behavioral rationale provided for these models bears even less cursory inspection than that in the Arifovic models. (Further evidence for this is provided by the fact that, as far as I know, there have never been attempts to fit game-theoretic models of this kind to any data or even to suggest social processes from which these data might be collected.) Replicator dynamics originated in theoretical biology, where they were intended to model shifts in the proportions of genes or species of differing fitness. In extremely simple terms, a gene or species will increase (decrease) its share in the population if its own fitness is greater (less) than the average fitness and the change will be proportional to the difference between the average and the particular gene/species fitness. All models of this kind face the same difficulty. Replicator dynamics is based on the assumption of an underlying biological process which justifies its mathematical form.^[53] For example, it is assumed that species display exponential population growth when they are not resource constrained. In applying such models to social processes, the results will only be useful if the same assumptions apply. Without exception, replicator dynamics models justify themselves with reference to discursive behavioral arguments about imitation and observation errors and not by reference to the other underlying assumptions of the original model. This produces a number of problems:

How do individuals get information about average fitness, or even observe the fitnesses of other individuals? Usually these models simply substitute an unexplained rational theory of imitation for a rational theory of individual game play.

How do individuals correlate game strategies with decision processes? In far too many models, this problem is assumed away. Either the individual just *is* their strategy, or else individuals are both telepathic and know the full set of possible decision processes. The latter assumption is required to ensure only legal mutations.

Biological models assume competition for scarce resources like food and shelter which directly impact on reproductive success through physical mechanisms. The possibility of making correlations between certain independently observable and measurable skills (like foraging rates) and reproductive success makes the concept of selection by reproductive success both non tautologous and potentially falsifiable, though this is very hard work outside the laboratory. In games, the resource "emerges" only in game play and its only value to the player is that it enhances the likelihood of strategy propagation. While a strategy like "co-operate" is observable and can be correlated with reproductive success (though with the reservation that this success

must actually be correlated with all possible strategy combinations), this correlation is meaningless because the only "measure" of the strategies performance is precisely the same "utility" which determines that success.^[54]

5.6

What lessons can be learnt from these unsatisfactory models? The first is that the interpretation of evolutionary models *does* matter on at least two levels. On the methodological level, very few unorthodox economists (or non economists come to that) subscribe to the "as if" argument for modeling, which states that it is irrelevant whether a model is behaviorally plausible as long as it predicts adequately. In any event, it has no force in areas like evolutionary game theory where predictive models are not available. It is not enough for those who believe in procedural rationality to know *what* happens, they also want to know *how* it happens. In that sense, an interpretation is just a more complete specification of the *process* by which evolution could take place in a social rather than biological context. On the practical level, although the Arifovic models *are* used to make limited sense of experimental data, the behavioral interpretations used are in the main either inconsistent or implausible. This could be avoided if the behavioral interpretation of the model was more than a rhetorical defense of the selected formalism. This brings us on to the second lesson, which is that a working knowledge of the history and implications of evolutionary biology and evolutionary algorithms appears to be important in their sensible application to social science.^[55]

Simulations Based On the Mental Interpretation

5.7

In this section I will discuss a series of models which appear to achieve a more plausible behavioral interpretation in the use of evolutionary algorithms. Simulations using the mental interpretation and based on Genetic Programming have been produced by Chattoe and Gilbert (1996), Chattoe and Gilbert (1997), Dosi *et al.* (1994), Edmonds (1997) and Edmonds and Moss (1996) among others.^[56] These models have been applied to the behavior of households learning to budget, firms setting prices in a market and modeling individuals who face an environment where having the same world view as everyone else is undesirable. Despite these differences, we can identify two sets of common questions which must be addressed by each of these models.

The Interpretation of the Agent Decision Process

5.8

All the questions in this group depend on how much detail can we provide about the "mental process" corresponding to an internal evolutionary algorithm. It is clear that for any problem, an individual or organization will have a number of candidate solutions which seem feasible. The reproduction operator corresponds to a process by which some candidate solutions become "more favored" in the population. The crossover operator corresponds to a process in which one candidate solution is modified by the incorporation of a sub tree of material from another. The mutation operator corresponds to a process by which some part of a candidate solution is

replaced by a *novel* sub tree or "innovation". All three operators require more detailed interpretation.

The Interpretation of Reproduction

5.9

How is the process of reproduction represented in the state of the population? We have already discussed in passing that the weights assigned to Classifier System rules can be seen as corresponding to the duplication of fitter strategies in a traditional GA. However, the behavioral meaning of strategy duplication is much less clear than that for some sort of weighting or "confidence measure" attached to particular strategies. In particular, there are empirical features of human cognitive abilities which do not correspond well to the duplication interpretation. The most important of these is the existence of long term memory. Although it is true that humans can hold rather few strategies "in mind" at any one time, they are extremely good at remembering strategies which they have already implemented or observed elsewhere. Thus the traditional GA or GP architecture, which implies parallel processing of operators applied to many candidate solutions is probably not appropriate for models of individual decision making.^[57] A behaviorally plausible alternative exists, in the shape of the GENITOR algorithm (Whitley 1989). In this algorithm, candidate strategies are permanently ranked by fitness. In each generation, instead of parallel processing, strategies are chosen proportionate to their ranking and a single operator is applied.^[58] Offspring of crossover and mutation are returned to the population at the "appropriate" positions indicated by their fitness. They either replace the strategies with the nearest fitness or are inserted into the ranking so that the least fit strategy "falls off the bottom". This approach has three advantages. Firstly, it explicitly avoids duplicates if strategies replace those with the nearest fitness or can easily be made to do so under the insertion strategy. The "importance" of strategies is represented by their position in the ranking rather by the existence of duplicates and insertion does not require the re-evaluation of fitnesses for all other strategies.^[59] Secondly, this ranking also remains relatively stable because operators are applied one at a time. (The flipping from strategy to strategy displayed by non converged traditional GA or GP is not self-evidently plausible as a representation of human behavior.) Finally, the algorithm relies on the "active consideration" of no more than two strategies at any one time, all other strategies are simply stored in memory. However, there is a drawback to this approach, for which detailed discussion will be postponed. In an instrumental GA, the fitness function is known and fixed so new strategies can be "placed" in the ranking immediately. It is not clear what should be done to them if fitness evaluation requires interaction with the environment. We will return to this point.

The Interpretation of Crossover

5.10

Is crossover to be proportional to some measure of fitness? If so, what measure? In the GENITOR algorithm we have already discussed, crossover is more likely to occur among solutions with higher ranking. In an organization, this could be interpreted as reflecting the number of people preferring and arguing for a particular strategy. In an individual, it could

reflect the fact that better strategies are more likely to "spring to mind" or remain in the forefront of memory. One thing to bear in mind is that once we become interested in descriptive models, it is more appropriate to consider what is realistic than what produces rapid convergence and this applies just as much to the parameters of the simulation as it does to the selection of the evolutionary algorithm. (We may even become interested in distinctive *failures* of convergence if these can be identified empirically.) Simulations are a very useful technique for comparing different possibilities in this context. This point is just as relevant to the assumption of strictly proportional fitness as it is to the size of the population of candidate solutions discussed in the last section. Just how much do we lose if the population is 5 rather than 50?^[60] How much slower would convergence be if solutions were only ranked as good, average and poor or if solutions were ranked with probabilistic accuracy?

5.11

If the exogenous fitness function used in the Arifovic and replicator dynamics models is regarded as imposing too much structure on the evolutionary process, then at least two alternatives exist. The first appears not to have received much attention. This would involve each individual using an internal fitness function which is nevertheless regarded as being "infallible" by that individual. Even if individuals have identical internal fitness functions, they avoid the problem of external teleology, but this approach also allows for the fact that agents may simply have different goals.^[61] In addition, it is possible to investigate how the environment selects fitness functions at the same time as it selects strategies which are fitter relative to those fitness functions it selects.^[62] One of the reasons why the "internal fitness function" approach has not received much attention is that it goes against an important assumption of most bounded rationality models, which is simply that agents cannot accurately rank the fitnesses of strategies *a priori* except in trivial environments. Instead, they can only evaluate strategies in use and make comparisons on the basis of what has already happened. This is the basis of the Dosi *et al.* (1994) simulation, in which firms use cumulated profits to choose GP strategies for price setting on a probabilistic basis, with a minimum probability for previously untried strategies arising from crossover or mutation on the current population. (Depending on how mutation is defined, it is capable of generating whole new strategies.) Strategies which fail on any one of three conditions will be replaced, either with new strategies or crossovers/mutations of current strategies. The first failure condition is that the probability for a strategy being picked should fall below a minimum value. The second is that a strategy should generate a negative profit. The third is that it should indicate a price outside a rather broad range of "sensible" prices which runs between 0 and some large positive value. This model suggests a number of points. Firstly, its functioning is rather similar to the GENITOR algorithm in that the methods for generating replacement strategies tend to preclude duplication and force out the worst strategies disproportionately. Secondly, there is negligible calculation involved in the decision process. All that is required is a running total of cumulated profits for each current strategy and maximum and minimum values for sensible prices. Finally, the model draws attention to the distinction between syntactic (genotypic) and semantic (phenotypic) evaluation of strategies. It is possible to reject a strategy because it generates what is believed to be a "silly" price without reference to what happens when it is tried out in the market. By contrast, trying it is the only way that a strategy can be found to be unprofitable. Although we have already cast doubt on the plausibility of internal fitness functions which are capable of ranking strategies, it is much more plausible that there

should be internal *filtering* processes that cut down the size of the strategy space based on general domain knowledge (McCain 1992).

The Interpretation of Mutation

5.12

Does mutation correspond to "transcription error" or experimentation? This is a relatively minor point, but it affects the fitness attributed to new strategies. In the Dosi *et al.* model, new strategies resulting from crossover are assigned the average of the cumulated profits of both parents. (This is the nearest that firms come to doing any calculation.) If mutation is interpreted as transcription error, then the mutant should be attributed the same cumulated profit as its parent since by definition such errors would be corrected if they were noticed. This could have unfortunate effects if a mutant was much poorer than a parent which had already cumulated a large profit. (In fact, this is one potential drawback with the Dosi *et al.* model, that firms have an infinite memory for cumulated profits, thus leading to possible lock in. On the other hand, as we have already remarked, evolutionary algorithms which produce too much strategy vacillation may be empirically implausible.^[63]) By contrast, if mutation corresponds to experimentation then all mutants should be treated as untried strategies or perhaps receive the parental fitness penalized according to some distance metric between parent and offspring.

5.13

This section suggests that with care, coherent interpretations can be produced for all the traditional genetic operators. These can be fitted together within the framework of the GENITOR algorithm, with some modifications to allow for the fact that strategies cannot be evaluated for actual fitness without trial. Strategies remain ranked by fitness (cumulated profit for example) at all times. New strategies are assigned a minimum fitness (or probability of being chosen) reflecting their untried status. Crossover products receive the average fitness of their parents. Mutation products are regarded as untried.^[64] The parents are chosen probabilistically on the basis of their ranking as is the strategy which is actually to be implemented. Tried strategies that yield negative profits or produce "silly" prices may still remain on the list as a mechanism to prevent their being reintroduced, but they will have no possibility of being chosen as parents or of actually being implemented. (Firms will reject crossovers, mutations and novel strategies if they have already been tried within institutional memory or are currently "under discussion".) This algorithm has a number of desirable features. Firstly, the probability distribution for strategy implementation need not be the same as the probability distribution to select parents for the genetic operators and neither needs to be equivalent to the institutional memory of the firm. For example, the implemented rule could just be the top ranked one at all times. This would make firm behavior very stable. For equivalence to the Dosi *et al.* model, parent selection would take place from the set of all strategies which had actually been tried and achieved a cumulated profit greater than the minimum for untried strategies while implementation would take place from the set of all strategies including the untried ones. Secondly, the evolutionary process is "driven" by the firm's view of its own institutional memory, without this making it a rational choice process. While the GENITOR algorithm performs one genetic operator every period, a firm will only attempt to identify new strategies when it is unhappy (in some sense to be defined)

with the set which it already has. If the firm always wants to entertain four possibilities, then initially it will have four untried strategies, but as it tries them, they will get ranked. Only strategies which perform so poorly that they are probabilistically less likely to be chosen than untried strategies (which are assumed to have a fixed minimum probability of being chosen reflecting their "curiosity" or "novelty") will encourage the firm to cast about for new ones. This also produces a measure of realistic stability into the behavior of the firm. Thirdly, this algorithm not only incorporates the coherent interpretation of the operators, but takes into account earlier comments about the distinction between institutional memory and active consideration, the behavioral implausibility of duplicate strategies, the limits on what firms can know and calculate and the possibilities for syntactic reasoning about strategies even when semantic reasoning is not possible. It should be made clear that this algorithm is only being proposed for further investigation rather than advocated as the *correct* model of evolutionary decision. It does however seem to have a number of desirable features which may make it worthy of further consideration.

5.14

In the next section, we turn from discussion of the decision processes of the agent to their interaction with other agents and physical processes in the environment.

The Interpretation of the Environment

5.15

So far, individuals under the mental interpretation have just been concerned with evaluating strategies they have generated "internally". Depending on the nature of these strategies, it is also necessary to develop a coherent interpretation of the individual's relationship with the environment of other individuals and physical processes.

5.16

The first issue arising in this context is a general one, concerning the open endedness of biological and social evolution and the way this compares with the functioning of evolutionary algorithms. *Prima facie*, it may appear that the problem with evolutionary algorithms is that they have a fixed set of terminals and operators while biological evolution does not. In fact, this is not the case. Within certain limits, like the coining of new scientific terms, any human language also has a more or less fixed set of components, though it is obviously far larger than the typical GP language. It is the *combination* and *structuring* of these components that can accommodate both the richness of sonnets and the pragmatism of operating instructions. However, neither richness nor pragmatism can be attributed purely to the combinations of words themselves. Instead, it results from some comparison between the words and some other aspect of reality. In the case of operating instructions, the words are compared with perceptions of the thing to be operated and feedback on whether implementing the instruction produces the desired result. In the case of a sonnet, the words are "compared" with memories of summer days and sweet spring showers to see if they evoke sensations appropriate to what the poet is talking about. In each case, it is the *interplay* of genotypic and phenotypic aspects that gives rise to richness. In an instrumental GP,

the fitness function just summarizes the environment. In a descriptive GP, open endedness arises not just from enlarging the GP vocabulary, but equally from enriching the environmental consequences of phenotypic behavior to which it gives rise. For example, instead of the terminals "pick up box", "pick up cone" and "pick up sphere" in a simple blocks world, we might have the terminal "pick up nearest" which, when applied, has consequences which depend on what the nearest object is. Of course, the environmental interpretation of "pick up nearest" is not immediately accessible to the agent who carries out the operation. In fact, for any sort of "pick up" terminal, it consists of the "physics" of the environment. All the individual observes is that "pick up nearest" usually works very well when the nearest thing is a pen, but results in a hernia when the nearest thing is a safe! It is on this basis that the individual may start to organize their perceptions and make inferences. (For example learning not to attempt "pick up nearest" on "big things".) This view of the relationship between agent and environment is described as qualitative physics and is essential to the existence of genuine novelty in the environment.^[65] In fact, as far as we can tell, the environment is not completely open ended but follows "natural" or "social" laws. The fact that nitric acid mixed with glycerin produces nitro-glycerin was "known" to the physical environment but not to Alfred Nobel, who blew himself up several times finding out! Thus, building open ended evolutionary algorithms is, perhaps paradoxically, a matter of increasing the sophistication of the environment and not of the agent.^[66]

5.17

This observation has an immediate application to the issue of what individuals are supposed to be able to infer or observe about each other. In the first place, it is important to distinguish *behavioral* imitation (where one firm simply imitates the price set by another in the last period for example) from *cognitive* imitation (where one firm is actually able to incorporate some aspect of another firm's decision process into its own). More research is needed in the extent to which firms are capable of making inferences about each other and actually do so.^[67] On one hand, a great deal of information about a firm is extremely hard to observe, even if it is not actively kept secret. Against this can be set the incentives for success and the considerable skill which humans have at making inferences. For example, one firm may infer that another is testing a new production process secretly by observing that it has started purchasing a certain sort of raw material in small quantities.^[68] It may make *this* inference by observing the delivery van of a specialist chemical company. In the light of these difficulties, transcription errors are a far more likely explanation of mutation than deliberate experimentation during the process of imitation. It is also clear that the syntactic "interpretability" of GP trees is important not just for the simulator, but also in ensuring that a firm "knows" when it has obtained a coherent piece of "intelligence", even before it can place a value on it. By contrast, GA models have to assume syntax preserving operators like crossover so that firms don't have to address the issue of interpretation. The qualitative physics perspective is relevant both in the process of making inferences as part of imitation - inference involves "filling in the gaps" using correlations that have been acquired from past experience - and in trying to assess who it would be appropriate to imitate. Again, more research could perhaps be done on what knowledge about firms can be regarded as available in the market, but we can be sure that even if the profits accruing to individual strategies are not available, firms will be attempting to build up proxies that define their competitors in terms of age, share dividends, recent expansion or recruitment, firm size and so on.^[69] All of these proxies can be defined in relative and not absolute terms.

5.18

The final difficulty in interpreting the environment comes in representing what individuals believe about the effects of their actions. Arifovic assumes by omission that firms don't have any beliefs about this and perhaps, since the only option they have is to set their own prices, this is appropriate. However, it may raise a problem with the election operator since this requires a firm to assume market stability in two interdependent respects. Firstly, the profit accruing to a strategy in the previous period must be positively correlated with its profit in the present period. Secondly, the impact which one firm has on the environment must not be so great that the profit accruing to it, had it used the strategy it is now testing for election, would have been completely different to the one it actually observed for the strategy it *did* use. These problems are avoided in the Arifovic models by the extreme simplicity of the environment and the effective "invisible hand" of the fitness function, but in real markets such assumptions of stability might not be appropriate. The same problem occurs with more force in a GP model of the El Farol Bar (Arthur 1994) developed by Edmonds (1997). In this model, each agent is keen to visit the bar only if it is not too crowded. Agents make use of mental models which allow them to decide about whether to go to the bar each night, based on previous experience. The preferences of the agents require the evolution of mental model diversity, since if *everyone* believes the bar will not be too crowded, they will all go and make it too crowded. In Edmonds (1997), despite the fact that agents are evaluating sophisticated GP strategies which take account of the past actions and utterances of other individuals, they perform evaluations on the assumption that what *they* do has no impact on the actions of those other agents! The kind of comparisons which it is appropriate for individuals to make will depend on the particular structure of the model, but it is important to devise comparisons which are both consistent and plausible. Again, the qualitative physics approach suggests that individuals will be attempting to *identify* stable comparisons which can then be used as parts of their decision process. We may choose to simplify the model by allowing only "appropriate" comparisons, on the basis of "external" observations of the model properties, but we should not ignore the issue altogether.

Simulations Based On The Population Interpretation

5.19

Population based models, which attribute a single strategy to each individual are obviously more appropriate to modeling norms or habits rather than sets of strategies which have any rational component in their selection. Many of the issues connected with models based on the population interpretation, such as imitation and the significance of the genotype/phenotype distinction have already been discussed. One obvious area for further research is models which combine evolution at the individual and population levels.^[70] At their simplest, however, individuals may only consist of a single action such as "co-operate" or "defect".

5.20

It should not be thought that replicator dynamics is the only technique for representing population level models. Apart from the reservations already expressed, it is straightforward to build models which more closely approximate to a coherent social evolutionary process. For

example, we can view the payoff to games in terms of "energy" rather than "utility".^[71] This is used up at a steady rate and any agent reaching a zero energy level is removed from the population. (This approach is used in the "sugarscape" described by Epstein and Axtell 1996.) Depending on whether there is more to agents than particular game strategies, performance based imitation can take place on the basis of proxies like age and involve behavioral imitation or inference of the genotype with imitation and mutation. It is not yet known whether models of this kind would arrive at different equilibria than the replicator dynamics models and this remains an unexplored field of study.

Syntactic and Semantic Evaluation

5.21

In addition to developing coherent interpretations of the decision processes of individuals and their interactions with the environment, there is also a more general issue of interpretation which needs discussion. This is the relationship between directed and undirected learning and the role of syntactic and semantic analysis of strategies. Syntactic analysis involves being able to say something about the value of a strategy purely on the basis of its syntax. An example was provided by a GP tree which indicates a negative price. This is obviously unsatisfactory and does not need to be tried out in the market. By contrast, semantic analysis involves being able to say something about the "meaning" of a GP tree, for example that the reason why a cost-plus pricing strategy is failing to show a profit is that the definition of the cost element fails to take account of depreciation in the form of intermittent costs for machine replacement. The obvious difficulties with semantic analysis have meant that descriptive GP models have ignored it so far. This has meant that in some sense, learning by alterations to GP strategies has been largely undirected. Although whole strategies are chosen according to past performance, the components which make them up are not selected on this basis, or at best only very indirectly. (Firms must implicitly assume that sub trees of better firms - where better is defined by their criteria on whether or not to imitate - are themselves on average likely to be better, but this is much weaker than being able to identify and imitate only fitter sub trees.) By contrast, directed learning involves being able to evaluate the choices one is presented with in some way and pick the better ones directly.

5.22

Although the development of models which include semantic analysis of GP strategies is a major project, one possible direction is indicated by the discussion of qualitative physics in the previous section.^[72] In the same way that what is lacking in open ended GP models is not more operators and terminals but a richer environment, what is lacking for the firm to perform semantic analysis is not some "special" GP language but adequate *internal* structure to the model of the firm.^[73] For example, if "costs" are categorized as actions which result in a reduction in the current account, then a comparison of this set with the set of terminals in the current GP strategy will reveal the absence of any terminal connected with machine replacement costs. Semantic analysis of strategies thus presupposes that the operators and terminals possess additional attributes which give them semantic content.

5.23

Semantic analysis also raises two other interdependent issues. The first is that figuring out what a GP tree means can also be a taxing problem for the simulator as well as for the individual that is using it. Some of this difficulty can be removed by sensible choice of operators and terminals and avoidance of very large trees.^[74] (Combinations of operators and terminals which are easy to interpret individually but hard to interpret as a tree may provide *prima facie* evidence against those combinations occurring in real decision processes given our evolved linguistic competence. Mixing logical and arithmetical operators in the same tree provides an obvious example.) However, some difficulty is bound to remain and this results from the fact that GP trees are single entities. They can be contrasted with CS rule bases in which each rule is simple to understand but the combined effect can be very complex, particularly if rules are able to alter the state of the message list so that new rules become eligible to fire. There is no simple resolution for this problem, which is no less than the long running knowledge representation debate from Artificial Intelligence (Brachman and Levesque 1985, Sloman 1985). However, research into ADFs may also provide some suggestions as to how useful sub trees can be identified and propagated more effectively.^[75]

Conclusions

6.1

This paper has had to draw in a wide range of ideas and examples to present a coherent framework for social evolution. However, to conclude effectively, it is possible to decompose the resulting framework into three constituents: the process of biological evolution, the instantiation of the evolutionary process in an evolutionary algorithm and the implications of both of these constituents for evolutionary models in social science.

6.2

On the first count, it matters very much whether one has an effective understanding of evolutionary biology in producing models of social evolution, both in recognizing the parallels between social and biological evolution and, equally importantly, acknowledging their differences. In this paper, I have focused particularly on three aspects of this understanding. Firstly, the importance of a proper understanding of Lamarckian inheritance, stressing that its absence in biology is only a contingent fact rather than a theoretical or logical necessity. Lamarckian inheritance not only fits smoothly into the *social* evolutionary framework but, correctly interpreted, resolves difficulties about the identity of units of selection and the likely speed of evolutionary change. Secondly, there is a need to avoid spurious teleological reasoning. Although it is true that social institutions, including the market, exert some selection pressure on individuals and organizations, it is not at all clear how strong that pressure is and whether it should be seen as congruent with any desirable social goals. Finally, it is important to be clear about the behavioral interpretation of processes of "genetic transfer" essential to evolutionary models, so that agents are assumed to perform actions that they seem likely to be capable of in the real world. There seems little point in moving from rational models of decision to equally implausible rational models of imitation.

6.3

On the second count, it is equally important to understand the strengths and weaknesses of evolutionary algorithms and to recognize their many variants. The majority of these have been developed with instrumental objectives in mind so caution must be used in applying them to social processes. This is particularly true of the fitness function which imposes an external teleology on the instrumental GA in a way that may not be appropriate for descriptive models. However, on a more positive note, the quest for rapid optimization techniques has led to many creative uses of the biological analogy in generating variant algorithms which have not yet been fully exploited in models of social evolution. One illustration is provided by the discussion of the GENITOR algorithm, a less well known alternative to the traditional "Holland type" GA, which is argued to be a more behaviorally plausible representation of an evolutionary decision process at least under the mental interpretation. Two other obvious areas of research which have remained unexplored to date are the possibility of inducing reusable subroutines in the decision process using the ADF approach in GP (Koza 1994) and attempts to implement any semantic (rather than purely syntactic) modification processes for decision trees, based on some background knowledge in the agent. It is also surprising, given the relative ease of interpretation for single rules compared to GA strings or GP trees, that genuinely social models based on CS have not been more extensively developed. (It is also possible that new developments in the modeling of social evolution will inspire new instrumental approaches.)

6.4

On the final count, despite the emphasis on economic models in this paper, it is clear that with certain reservations, evolutionary modeling is appropriate to the other social sciences too. The most important dimension of difference between the disciplines is the degree of deliberation assumed to be involved in social action and the role of others in the decision process. However, it is clear that imitation and mutation processes are if anything even more appropriate for representing mechanisms of social influence or conformity. Since most descriptive models of social evolution dispense with the global fitness function, they can be used equally well for rather economic approaches involving a well defined utility function as for more social approaches based on reference points or aspiration levels. It has already been remarked that the more "cognitivist" approach is capable of drawing the different social science disciplines more closely together, at least in principle. This suggests a whole new field of modeling in which attempts are made to *integrate* the insights of the different disciplines within a simulation framework. (One example is provided by Chattoe and Gilbert 1997). Another relevant area of research that has not really been touched on in this paper is the use of *neural networks* to model the evolution of social processes. Like the use of evolutionary algorithms, this research is mainly concentrated in unorthodox economics (Margarita 1992, Beltratti *et al.* 1996), but there are also simulations which can be seen as modeling "low level sociality" and could be assigned to economics, sociology, anthropology or even archaeology (Parisi 1997, Pedone and Parisi 1997). The reason for neglecting these approaches is not that neural networks are an inappropriate way of representing agent competencies, that depends very much on the behavior concerned and on disciplinary preferences for models of conscious deliberate action or instinctive, behaviorist and socially contextual response. Rather, the difficulty is that there is little analysis of how the evolved neural networks do what they do. By contrast, far from being a black box, some

accessible and conscious (though plainly not fully rational) mental process is widely believed to be what makes social action distinctively social. Be this as it may, neural network models draw attention to the fact that social evolution does not need to imply a rational or cognitivist view of agents.

6.5

In addition to these individual observations about the three components of the synthesis, an overarching conclusion can tentatively be drawn: that a coherent and complete interpretation of social evolution can at least be sketched. Furthermore, it is possible to move the debate on from the conceptual or methodological level (where some of the misunderstandings originated with contemporaries of Darwin) to the implementation of some concrete models which have been illustrated in this paper. Applications of evolutionary algorithms in new areas can do nothing but sharpen the debate further.

6.6

Finally, however, it seems appropriate to conclude a speculative paper such as this not with a definitive conclusion but rather with two unanswered questions, one empirical and one theoretical:

Just how much teleology is there in social organizations like markets? On one hand, it is clear that markets do not enforce profit maximization. On the other, it seems to be constitutive of a competitive market that firms must satisfy the minimum requirement that they cover costs, at least in the long run. Because, at least theoretically, bounded rationality permits us to envisage a world in which everybody has a completely different cognitive model, we can see the considerable social advantages in agreements to set up institutions binding everyone participating in them to relatively similar behavior. What can we say about the status of evolutionary processes taking place within these institutions? The answer has to be empirical rather than ideological. Diversity provides some guidance to the evolutionary pressure being exerted, though with the qualification that firms may respond to this pressure by specializing and deliberately occupying different niches. Simulations which explicitly model the processes by which social structures like markets come to be legislated might provide another fruitful field for future research.

To what extent should evolutionary algorithms (GA strings, CS rule bases and GP trees) even be *expected* to represent the whole process of decision? In particular, should we be thinking about the development of *hybrid* systems in which the processes of identifying and testing regularities to serve as operators and terminals would be carried out in parallel and using different techniques to the process of evolving good strategies based on those operators and terminals? Neural networks are an obvious technology for identifying patterns in data and could be seen to correspond to the innate (and largely unconscious) human ability to recognize patterns.^[76] GP technology can also be used in the same way. In particular, we can envisage a firm devoting its "Statistics Department" to the task of predicting what other firms (or "the market") will do. If these predictions ever attain an adequate quality they will be incorporated into the strategy of the firm that has developed them. (Of course, this may not work for long if the other firms are doing

the same!) This self prediction technique can also be applied instrumentally and descriptively to the task of understanding GP trees. The task of a subsidiary GP would be to predict the behavior of a complex GP tree, either using the same language or a simplified one. The subsidiary GP is rewarded for the quality of its prediction but heavily penalized for tree depth thus enforcing simplification. Instrumentally, this technique may be added to the automated syntactic simplification traditionally practiced on GP trees, where (* 1 (...)) is replaced by (...) for example (Koza 1992a). Descriptively we can imagine firms continuously trying to identify predictable sub trees in their strategies using both syntactic and semantic techniques.

Acknowledgements

I would like to thank Bruce Edmonds and Luigi Marengo for helpful discussions of their models which are described here (Edmonds 1997, Dosi *et al.* 1994). Any errors of interpretation remain my responsibility. My thanks are also due to the editor and two anonymous referees for their helpful comments.

Notes

¹ This term includes, but is not restricted to, Genetic Algorithms, Evolutionary Strategies, Genetic Programming and Classifier Systems. For further useful discussion see Nissen (1993).

² Orthodox is used here in the sense defined by Nelson and Winter (1982).

³ There are, however, some fascinating exceptions (Bagehot 1887).

⁴ The earliest paper satisfying this definition is generally agreed to be Alchian (1950).

⁵ Although genetic "fitness" is typically associated with numbers of live offspring, the tendency to reproduce as often as possible may be an effect as much as a cause of evolutionary selection, which merely requires persistence. Although the first species that began to reproduce rapidly would gain an advantage against species which did not, no species could gain any further advantage once rapid reproduction was universal.

⁶ This is a simplification. There are actually several processes by which genetic mixing and mutation take place, corresponding to various things which can happen to the chromosomes (Weaver and Hedrick 1992: 87-94). In asexual reproduction there is no genetic mixing. However, asexual reproduction is limited to simple creatures and sexual reproduction can itself be seen as an evolved mechanism by which genetic mixing can take place if it is beneficial.

⁷ The validity of the assumption that social behavior is no more than the sum of individual interactions remains contested in social science. Although economics favors a purely individualistic interpretation, sociologists sometimes appear to argue that norms and other social influences are more than the sum of individual mental contents.

⁸ We can thus see the ability to make these attributions and cultural (rather than genetic) transmission of behaviors as evolved mechanisms which reduce the wastefulness of the

evolutionary process. Instead of "throwing away" a whole individual, it is possible for that individual to both identify and modify particular aspects of behavior that are persistence threatening. We would expect these features to be both a cause and a consequence of increasing complexity. As individuals become more complex and the potential for diversity increases, it becomes more wasteful to "throw away" whole individuals. At the same time, self awareness and cultural transmission dramatically speed up processes of experimentation in relation to the environment, which were previously restricted to one "try" per lifetime.

⁹ Note that *progressive* increases in complexity are not implied. That depends on whether a species with a given level of complexity persists robustly against all simpler organisms and their subsequent developments. So far, humanity appears to be in this position, but only so far.

¹⁰ The traditional example is that the children of hard working blacksmiths might be born with extra muscles. But equally the children of amputees might be born with missing limbs.

¹¹ Lamarckism arose before genes were discovered. It persisted, rather uneasily, when there still appeared to be a simple mapping between genes and "traits" like blue eyes, but has not survived the discovery of detailed biochemical mechanisms of development.

¹² They may even be meaningless (Tintner 1941a, Tintner 1941b) or incalculable (Thomas 1993).

¹³ It will be recalled that the evolutionary process implies nothing about whether competitive or co-operative strategies will tend to persist more effectively (Kropotkin 1939).

¹⁴ Conceptual smoothness merely implies that we do not need to postulate any uncaused causes or mysterious jumps. It is no more than "good science" writ large. Although we will never know what went through the mind of the person who invented the wheel at the crucial moment, we can be confident that it was something to do with what they knew and had experienced, seen or perhaps been told. Although the discovery of fire may have caused an enormous discontinuity in social practices, there is no conceptual discontinuity implied by its discovery and application.

¹⁵ These were also chosen because they are the techniques used in most of the evolutionary modeling done in social science to date. Other related techniques include Evolutionary Programming (Fogel *et al.* 1966, Fogel 1991), Evolution Strategies (Rechenberg 1973, Schwefel 1981) and Simulated Annealing (Davis 1987).

¹⁶ Random generation is compatible with the conceptual smoothness of the evolutionary process in obliging the population of individuals to begin in a state of maximum disorder.

¹⁷ This interpretation has however been challenged by De Jong (1992).

¹⁸ This analogy raises an interesting point. It is *assumed* that the meat yield of cows is a purely genetic matter, just as it is assumed that an instrumental GA process can have a fixed fitness function attributed to it, as it clearly can in the simplest cases. If it turns out that meat yields are affected by the "social" organization of the herd or that the fitnesses of population members actually affect each other, then the instrumental approach is an *empirically* invalid choice.

¹⁹ One reason for this is that the tree representation translates directly into a nested bracket representation suitable for list processing languages such as LISP.

²⁰ There are GA techniques which make use of variable length representations but they are typically unwieldy. See Harvey (1992) for further discussion.

²¹ It is hard to say conclusively that a GP tree is more expressive than a GA string, since any arbitrarily complex encoding for the GA can be hidden away in the fitness function. However, it is intuitive that the GP tree and the fixed "meanings" of its operators *taken together* are likely to be more economical than such an arbitrary encoding.

²² It is clear that this is a drawback for an instrumental GA which should ideally solve a problem as quickly as possible. However, it may not be a drawback for a GA used descriptively since it corresponds *prima facie* to human behavior in focusing on important issues first. In practice, this analogy does not bear close inspection and other unrealistic aspects of the simple GA, such as the exogenous fitness function, are far more damaging to its use as a descriptive model.

²³ This can either mean that the program is "self executing" or that a process of interpretation and execution is *internal* to the individual. Either interpretation also requires some distinction between the genotype and phenotype.

²⁴ We can distinguish three interpretations of the robot controller example. In the first, both the environment and the controller are "abstract" and exist purely within the GP. In the second, the controller remains "abstract" but there is also an attempt to simulate a real environment in which the controller will evolve. In the third, the GP is actually a program inside a real robot, operating in a real environment.

²⁵ Social science seems to give inadequate general attention to differing degrees of the social. Although it rightly has no interest in situations where a single individual interacts purely with a physical environment, it offers little by way of guidance as to how we might expect behavior to change as we move from agents interacting predominantly with an environment to agents predominantly interacting with each other.

²⁶ An interesting paper using this approach, applied to zoology rather than social science, is Koza *et al.* (1992).

²⁷ This description follows Nissen (1993).

²⁸ The structure of individuals could be subsumed straightforwardly into a GP, but not the operations which are carried out on those individuals.

²⁹ For the technicalities of this process, the reader is referred to Holland *et al.* (1986). Rules which fire and result in a good outcome "share out" the positive feedback, as do those which result in negative feedback. This sharing discourages bloating of the rule base.

³⁰ A GA which generates diverse populations to solve problems collectively is discussed in Smith *et al.* (1992). It is an interesting question whether the syntax of GP makes diverse populations redundant, impractical or neither.

³¹ Although the GP may produce a program that is equivalent to (rule1 AND rule2 AND rule3), it has no endogenous process to ensure hierarchical comprehensibility, so even if the operators are designed for easy interpretation, there is no guarantee that the overall structure will be easy to interpret. Furthermore, as the depth of the GP tree increases, so does the number of equivalent trees. These can be seen as potential drawbacks of GP representations which may be addressed by current research into program modularization through ADFs (Koza 1994).

³² The prevailing view that bounded rationality involves no more than applying rational principles to the process of cognition seems both incompatible with the bulk of what Simon wrote and incoherent on closer inspection, for precisely the reasons that Simon gives.

³³ In addition to the obvious point that these models are empirically very implausible!

³⁴ An example is provided by the history of atomic theory, where compounds were explained in terms of molecules, composed of atoms, composed of neutrons, protons and electrons, composed of quarks, composed of ...

³⁵ There may also be a signal extraction or credit assignment problem when an agent co-varies rules and meta-rules while trying to make sense of the environment.

³⁶ For a simple illustration, consider an individual who has a gun with a laser sight trained on him by a distant assassin. The assassin is so far away that they cannot be seen directly, but the reflection of the laser sight can. If the reflection can be seen near the target, the rational action is to take cover, otherwise it is to try and move to locate the assassin. Unfortunately, if the assassin trains the laser on some part of the victim's forehead, which is the best way to be sure of a kill, the only way the victim can see it is by holding up a mirror which, we suppose, is of such a shape and size that using it to look for the reflection will block the beam. Even if the blind spot is tiny, the victim will certainly die, despite having a rational decision process, because they have no way of simultaneously or sequentially observing the location of the reflection and the effect which the mirror is having on the beam. Admittedly, this example relies on an assumption about the shape of the mirror, but recall that its object was only to explain why even the smallest blind spot can destroy the possibility for rational action as economics defines it. In fact, one could argue that the shape of the mirror is consistent with defining some part of the forehead as a proper blind spot in the first place. A blind spot is more than somewhere you can't see when not looking in the correct direction! (Even if the victim had a second mirror of the same size and shape, and was very dexterous, they still could not use that mirror to observe the effect the laser was having on the back of the first mirror because it would then be the second mirror blocking the beam.) These ideas are developed further in work on "autopoietic systems" (Varela 1979, 1991).

³⁷ However, they can be justified in *other* ways, for example as biologically evolved competencies. Unfortunately, this seems rather an admission of defeat as far as social science is concerned.

³⁸ This raises another interesting issue. Although one agent is hampered by the difficulties of obtaining adequate information about another, it does not suffer from any *conceptually necessary* blind spot in observing other agents. (It is an open question whether the blind spot of the first agent will definitely impair its understanding of the second.) It is truly the case that others may know us better than we know ourselves from a logical point of view!

³⁹ The same logic applies to any models constructed by the social scientist. This view also implies a coherentist rather than positivist notion of truth.

⁴⁰ Note that *common* knowledge of this shared correct model, which enables it to form the basis for rational action, is an even stronger assumption than that agents all merely happen to have the correct model (Parikh 1990).

⁴¹ There is an obvious but very important difference between the assumption that individuals *do* what they intend to do and that what *happens* is what agents intend. The fact that it is possible to miss this difference is illustrated by the argument between Alchian (1950, 1953) and Penrose (1952, 1953).

⁴² Although we are concentrating on cognitive irreversibility, it is obvious that irreversibility relating to autonomous physical processes (Georgescu-Roegen 1971) can also be part of the same framework.

⁴³ As Nelson and Winter (1982) have pointed out, orthodox economic theory struggles with genuine novelty. We will have return to this issue as the same problem appears to beset simple evolutionary algorithms.

⁴⁴ An example is provided by the discussion of "big players" in Koppl and Langlois (1994).

⁴⁵ Friedman (1953) argues that the assumption that firms are profit maximisers can be justified by the fact that the market will tend to eliminate those firms that are not. This pseudo-Darwinian argument is still widely believed, despite being convincingly refuted by Witt and Perske (1982) and Chiappori (1984) among others. Ironically, the error in Friedman's reasoning is one that originates with Herbert Spencer over a hundred years ago!

⁴⁶ Although the abstract theory of the market may imply a universal framework of law standardizing the behavior of firms, a more detailed view reveals a rich structure of compliance, evasion, detection, political action, punishment and resistance. A question for the future is the extent to which more or less generally agreed but not universal practices *can* be said to constitute an external teleology and whether or not different degrees of agreement can be detected in the dynamics of different social processes.

⁴⁷ The minimal condition for market persistence is rather similar to that in biological systems, that the organism should "cover costs". Discussion of the widely held but mistaken belief that evolution produces optimal behavior can be found in Hodgson (1991).

⁴⁸ There are some extremely interesting and widespread developments in industrial organization which can be considered in evolutionary terms. The first of these is the existence of firms which develop by merger and buy out rather than pure production. The second is the existence of franchises and chains which really do reproduce branches whose operating practices may or may not be appropriate to their locales. These chains have to "trade off" economies resulting from common practices against loss of sales from local idiosyncrasies. They also have to consider the "carrying capacity" of the environment in siting their new branches.

⁴⁹ We should not perhaps presume on this issue, economic socialization is still inadequately explored and although long run historical analyses of the nature of the firm do exist, these are largely discursive.

⁵⁰ Another interpretation is that if firms know that the encoding is common and that the fitness function is one to one, they can work back from what firms did to what their GA string must be, although this raises issues about timing. Perhaps telepathy is a more behaviorally plausible assumption after all!

⁵¹ If we assume sociable agents then intentions *are* transmissible, but it is not clear how accurate measures of utility could be transmitted, even with the most active desire to communicate. Transmission of information about money amounts is obviously not helpful!

⁵² It should be noted that not all game theoretic evolutionary models are based on replicator dynamics.

⁵³ Other differences between economic and biological games are discussed by Selten (1993).

⁵⁴ One could view replicator dynamics as a purely instrumental technique on this basis. Once it is assumed that all individuals are utility maximisers and it is utility which determines propagation, the attainment of game equilibria is a foregone conclusion. If, as many users of replicator dynamics argue, its important contribution is to show *which* equilibrium occurs, then it is no longer possible to argue that behavioral assumptions about the process are irrelevant.

⁵⁵ One could diagnose the convergence problems in the Arifovic models knowing nothing at all about its interpretation.

⁵⁶ There are a number of models based on GA which avoid one or more of the shortcomings of the Arifovic models, for example Curzon Price (1997), Lomborg (1992) and Vriend (1994). Space considerations preclude their detailed discussion here, but some of the comments on GP models will also raise issues appropriate to those using GA techniques. In what follows, GP terminology will be used for simplicity.

⁵⁷ Edmonds (1997) uses a population of 40! Two additional comments can be made on this observation. The first is that because most of the cost of executing an instrumental GP comes in evaluating strategies, the actual coding of the GP involves deliberately *not* evaluating duplicate strategies, but using a hash table to weed out strategies that have already been tried (Koza 1992a). Even using this technique cannot avoid the wastefulness of strategies which are semantically equivalent but syntactically different. The second is that the number of strategies which can be "borne in mind" is far greater in a firm, where these would correspond to the views of particular individuals in the firm. The weights of strategies could then correspond to the number of people arguing for a particular view or their importance in the hierarchy.

⁵⁸ Rank based selection has the advantage that selection pressure does not drop as the population converges (Whitley 1989). It is an interesting question whether this also applies in social situations.

⁵⁹ This is trivial for a static fitness function, but not for a descriptive simulation in which fitness may change.

⁶⁰ This issue is discussed from an instrumental perspective by Reeves (1993).

⁶¹ One interesting possibility is that common knowledge may be mimicked by the fact that individuals tend to project their own models onto others. If, in fact, everybody did have the same model, this would be as good as common knowledge for the purposes of deciding what to do. Of course, it would fail miserably if models differed significantly. Perhaps this is why people have wars over religion rather than food.

⁶² In implementing a version of the Dosi *et al.* (1994) model, I followed them in assuming that firms selected strategies probabilistically on the basis of cumulative profits. When the strategies simply consisted of fixed prices rather than GP trees, all the firms quickly learnt to set the maximum price they could and rapidly priced themselves out of the market. Although there was an equilibrium with everyone charging the maximum permissible price, it was never observed because it required that all firms initially charged that price and did not deviate. This is an example where the fitness function for firms was not a complete representation of the restrictions on the market and thus prevented any firms from persisting. In this case, firms valued positive profit without limit but placed no value on market share at all.

⁶³ It is also the case that retention of profits *does* make firms far less susceptible to whatever discipline the market imposes and also perhaps more able to influence the terms on which market discipline is applied. This point seems to receive inadequate attention from evolutionary market apologists. Since this escape from discipline reflects the very success of firms, perhaps it is true as Marx suggested that competition, if not capitalism contains the seeds of its own destruction!

⁶⁴ They can be assigned the fitness of their parents providing that firms do not have an infinite memory for cumulated profit.

⁶⁵ The relevance of qualitative physics is illustrated in a paper by Sims (1991). This describes a simulation in which artificial organisms constructed of rigid blocks and joints are "evolved" to

perform simple tasks like "capturing" food. Rather than seeing the properties of joints and blocks as attributes of the organism, as classical Artificial Intelligence might, these attributes are modeled as functions of environmental factors such as "gravity" and "mass". The result is that the behavior of arbitrary evolved combinations of blocks and joints is always defined.

⁶⁶ This conclusion is also reached in the Artificial Life literature (Langton 1989, Langton *et al.* 1991, Langton 1993). Complex environments have another interesting effect. Because evolutionary algorithms are very good at optimization, they can often produce strategies which, in being self-evidently silly, reveal something about the inadequacy of the environmental specification. Developing the simulation thus becomes a co-evolutionary process, with behaviorally implausible strategies sometimes revealing unrealistic assumptions about the agent and sometimes about the environment.

⁶⁷ This distinction is often badly muddled in replicator dynamics models. If individuals just are their strategies then there is no difficulty, except that this is a very unrealistic view of individuals. If there is a difference between the strategy and the actions it produces, then strong knowledge assumptions are required to avoid worrying about how inferences can be made from actions back to strategies.

⁶⁸ In one firm where I worked, employee research group membership was not listed in the internal phone directory so nobody outside the company could get an overall picture of the amount of research being done in different areas!

⁶⁹ In Chattoe and Gilbert (1997), agents learn how to budget by evolving budgeting plans individually, but they are also able to observe the consumption patterns of other agents. The result is a co-evolution of effective budgeting plans and stratified lifestyles based on income.

⁷⁰ There is an analogy here with the highly instrumentally effective Island Model class of Genetic Algorithms in which relatively small populations evolve in parallel, but transmit their best strategies at random to other populations from time to time (Gordon and Whitley 1993).

⁷¹ Another way of seeing the issue of profits reducing the competitive pressure on firms is to ask whether profit tends to "evaporate" or not. Individuals can never achieve more than a certain level of energy or wakefulness and this continues to drain away whatever they do.

⁷² This program is proceeding for instrumental GP in the development of ADF techniques (Koza 1994) which may provide interesting insights which descriptive models can use.

⁷³ There is an obvious role here for the sort of computational organization theory models devised by Carley and others (Carley and Prietula 1994).

⁷⁴ Large trees are behaviorally implausible as well as almost impossible to interpret. An additional danger, suggested by the Dosi *et al.* results on price tracking is that a large GP tree may just become a lookup table for the state of the present environment. There has been little research so far on pulling GP trees that are apparently successful out of one environment and putting them in another.

⁷⁵ Another consequence of semantic analysis is the possibility of analogical reasoning. If a sub tree has a "meaning" attached to it, like "total costs" it becomes possible to substitute one sub tree for another in a way that is somewhat directed, as it relies on similarities of meaning. This also applies at the level of whole GP trees, which may only produce a number as output, but it is the use to which the organization puts that number which determines its meaning. Thus a tree that solves one environmental problem may be more likely to solve an analogous problem.

⁷⁶ Work of this kind could make use of research such as that by Sun and Bookman (1993) on the integration of neural and symbolic processing.

VIRTUAL URBAN LEGENDS: INVESTIGATING THE ECOLOGY OF THE WORLD WIDE WEB

By
Edmund Chattoe

International Conference: 25-27 March 1998, Bristol, UK
IRISS '98: Conference Papers

Introduction

This paper traces the evolution of several ecological phenomena connected with the spread of replicating messages on the World Wide Web (web) and Internet (net). The paper begins by discussing some basic ecological and evolutionary concepts and then turns to analyzing common features of replicating messages which have adapted them to survive in these particular 'ecologies'. Specifically, replicating messages survive best when they take advantage of the altruistic and 'information sharing' ethos of the virtual world, when they deal with issues of universal interest (most commonly the maintenance of the web and net themselves), when there is a steady influx of non immunized transmitters, and when it is difficult to falsify the content of the message definitively. (Certain very successful replicating messages share features of urban legends as suggested by Woolgar and Russell in their analysis of computer virus stories. In particular, a strong belief that some of these stories 'ought' to be true dramatically decreases the effectiveness of resources like hoax warning web pages.) These features can be illustrated by specific reference to the developments of the replicator known variously as xxx-1, Join the Crew, Win a Holiday or Good News. Good News is interesting because it is the warning and not the (probably) fictitious virus which constitutes the replicator. The paper concludes by drawing out the more general implications of studies of replicating messages. Firstly, the dialogues about these messages which occur on newsgroups are a very interesting source of secondary data about the transmission process which can be considered from the perspective of Conversation Analysis and Social Construction. Secondly, it may be appropriate to consider web phenomena like replicating messages from an 'ecological' perspective. Thirdly, the web serves as an extremely useful research tool for the study of replicators. (It may help to operationalise research on the spread of the memes suggested by Dawkins.) The paper concludes with some thoughts on the design and ethics of a 'tracer' or replicator deliberately released for research purposes.

Evolution, Memes and Messages

The genetic theory of evolution by natural selection (Darwin 1968, Fisher 1930, Edey and Johanson 1989) has three important elements for the purposes of this paper:

The Distinction between Genotype and Phenotype: We consider a population of individuals, each of which consists of a *genotype* and a *phenotype*. The genotype is a set of 'instructions' for constructing the phenotype. In biology, the genotype is the DNA which organizes chemical reactions to produce enzymes and other chemical compounds which in turn organize the division of cells and construction of the body during gestation.

Mechanisms of Genetic Variation and Propagation: The genotype is transmitted through reproduction. Certain mechanisms ensure that some genotypic traits are propagated relatively intact between parents and offspring - for example eye or hair color in families. Other mechanisms induce mixing of genotypes - for example children having aspects of *both* parents in their appearance - or the introduction of the generation of novelty through mutation as can be observed in the breeding of new roses or pedigree cats and dogs. Mixing of these two kinds of mechanisms - propagation and variation - is essential to continuing evolutionary success. Too little genetic novelty and variation can lead to inbreeding, observed in isolated communities, while too much, in the form of birth defects, results from such harmful environmental effects as excessive radiation. At any time, in a population of individuals, there is always a certain amount of genetic diversity leading to phenotypic diversity.

Processes of Environmental Selection: Because the genotype constructs the phenotype, variations in the genotype lead to variations in the phenotype. For example, a mutation in the genes may lead to an individual with an abnormally long neck. This may be helpful or harmful to the persistence of the individual and this in turn to its ability to reproduce others of its kind. In the case of a longer neck, we might expect a grazing animal to reach food not available to others of the same species. Over time, phenotypic aspects which are helpful to individuals will persist and spread, while those which are not will tend to be removed from the population. This process is caused by the environment. It does not reflect any deliberation by the creatures concerned.

As Dawkins (1976, 1983) has pointed out, this theory has two interesting implications: The first is that, rather than seeing the genes as mere passive carriers of genetic information, we can also regard them as 'selfish' puppet masters, building our bodies for the sole purpose of propagating themselves. Obviously, this rhetorical device must be treated with a certain amount of caution, the genes do not 'decide' or 'intend' to do anything in any accepted sense. Nonetheless, it can be useful to reverse the usual perspective and consider bodies as a mere by-product of genes rather than the other way around. (This reversal is also encountered in two everyday jokes: 'Mankind is water's way of getting from place to place' and 'Computers will never try to wipe out mankind. We are their sex organs.') This shift in perspective gives rise to one particular insight, which is that evolutionary biologists have tended to see certain processes as *causes* of natural selection when they can perhaps more usefully be seen as *effects*. Darwin deduced the 'struggle for existence' from the observed geometric increase in populations which are not resource limited. However, from a genetic point of view, the inclination to reproduce as frequently as possible might itself evolve as a way of reducing the species effects of individual death and securing a greater proportion of resources from other species which did not have this trait. Dawkins argues that the minimal condition for evolution is just *persistence* and that all this requires in turn is *replication* or *self-reproduction* when individuals have a finite life span. Thus, we see the 'replicators' proposed by Dawkins, as any objects which are 'able' to copy themselves or 'get themselves' copied in such a way as to persist in a particular environment.

The second implication is that processes involving replicators need not be restricted to biological systems. Dawkins coins the term 'meme' for a *social* replicator, the examples he uses being tunes or jokes. A 'successful' replicator in this context is a tune or joke which can 'get itself' transmitted continuously. An 'unsuccessful' one is not passed on and is forgotten. These ideas also arise in a number of other contexts. Lynch (1996) provides extensive discussion of belief transmission

processes of this kind. More general application of ideas of this kind have also given rise to the discipline of Memetics. Brunvand (1984) has collected many examples of 'urban legends' which, it is argued, propagate not because they are 'true' or necessarily 'useful' but because they identify our archetypal fears and concerns in such an effective way that they tend to be passed on readily. (From the selfish replicator perspective, this gives a whole new meaning to 'playing on our fears'.) Although much work is done in presenting these and other extraordinary narratives as 'factual' (Wooffitt 1992), the transmission of urban legends can be distinguished from related processes which are more generally treated *as* factual, such as the propagation of 'factoids' (such as The Legend of Tailor Pink, Petronius Arbiter, Time Traveler and Monkeys and Typewriters.) in everyday conversation or the persistence of erroneous 'standard interpretations' in academic literature (These distinctions themselves suggest another interesting analogy with evolution in biology. There is no rigid distinction between many 'observably different' species at the genotypic level. Instead, species are defined functionally by their ability to interbreed. Although it is straightforward to distinguish a 'factoid' from an 'urban legend' in terms of the function it serves in communication, the beliefs that it supports and the work that is done to warrant it, from the replicator perspective the two kinds of messages are functionally equivalent. What separates them is the inability to warrant an urban legend in the same way as one does an academic interpretation.)

In the next section, we turn to the possibilities for applying these ideas to the study of communication on the web and net.

Propagation Processes in the Virtual World

The mechanisms by which DNA replicates during cell division and reproduction provide both stability and variation in subsequent copies of the original genetic material. Stability is provided by the mechanical process of transcription which ensures that copies of DNA strings are typically very close to the originals. By contrast, strings of genetic material can become physically 'tangled' with the result that the 'tails' of two strings become attached to different 'heads'. These processes have analogues in the transmission of web and net information. The possibilities of 'cut and paste', forwarding and reply of emails, provide obvious opportunities for highly accurate transcription. At the same time, the transmitter has the ability to add, alter or delete information without this necessarily being visible to subsequent recipients. This alteration may be with deliberate intent to alter the content of the message or this may arise inadvertently, as when, in altering the formatting, a section of the message is unintentionally deleted. (If the reader is unconvinced they should do an Alta Vista search for a piece of text like 'infinite binary loop' from Text 1 below. The number of variations is surprising.) The same is true of information provided on web pages. (However, the situation is slightly different here, since if the person who copies the 'message' has no interest in modifying it or claiming it as their own, they may simply provide a link to the original page.)

We can thus distinguish between different kinds or levels of replication. Whole messages may simply be forwarded or transmitted verbatim. Particular parts of a message may be separated from the original and continue to propagate, for example in an exchange of emails forming a 'conversation'. (This process can also be seen in the way that quotations 'come adrift' from the larger works which produced them. In time, these quotations may take on a 'life of their own'

isolated from the qualifications of context.) Finally, a message may be propagated in a way that continues its 'tone' or 'subject' matter, while not necessarily retaining too much of the original text. (The obvious example of this is the children's game of Chinese Whispers, in which children pass a whispered message in a circle for the fun of hearing it strangely transformed.) These processes have historical analogues in the study of other kinds of messages and it is interesting to see how the mechanical nature of the transmission process affects the balance of propagation and variation. Hand written manuscripts of any length can often be dated fairly accurately, at least in relative terms, by studying interpolations, idiosyncrasies of the copyist, responses to damage in the original, and so on. By contrast, there is little variability in the text between copies of modern printed books, at least for the same edition. Things like photocopying and scanning are at an intermediate level of variability. It is possible, but tiresome, to produce composite images which can then be transmitted. Entertaining computer applications such as the 'Dancing Baby' are widely transmitted, but with no variation at all.

From the research point of view, there are several reasons why studies of replicators on the web and net are particularly appropriate:

Volume of Traffic and Speed of Transmission: Although it is possible to study hand written manuscripts or the ways that stories or historical events change their published form over time, data of this kind is very 'thin' in both spatial and temporal terms and the records, as well as the messages they contain, may be susceptible to selection mechanisms. By subscribing to lists, newsgroups, archives and so on, researchers may expose themselves to as large a volume of messages as they can handle. In addition, because of the rapidity of transmission, experiments on the spread of new ideas can be done over a realistic time scale

Compatibility and Anonymity: One of the defining features of both web and net is their high levels of compatibility in message transmission. If one wished to study the transmission of photocopies, it would be necessary to seek out and become a part of some social group in which photocopies were routinely made, such as a large office. Even here, the number of 'instances' would be small and there would be no non-intrusive way to ensure that one was able to observe a representative sample. Any findings which resulted would not necessarily be useful in other organisations. By contrast, the relative anonymity of the virtual world means that one can easily observe transactions on many different newsgroups as well as collecting more anecdotal data in the normal course of being a web or net user.

Accessibility: One of the most remarkable features of the web and newsgroups is the fact they are now indexed down to the level of individual words by search engines. This permits particular strings of text to be identified and located for the purposes of studying speed of transmission of replicators. Because of the enormous numbers of sites involved, it may even be reasonable to hope that there is some statistical reliability in any findings, for example that the number of instances of a particular message which have found their way into archives are an accurate measure of the volume that were transmitted but not stored.

These dimensions also allow us to compare web or net research with other forms of research that are traditionally done. Historical or documentary research suffers from much lower accessibility and speed of transmission. Laboratory experiments have far higher accessibility but anonymity

(complete or even partial) is often considered unethical. Participant observation or ethnography also has advantages in respect of accessibility but their status in term of anonymity is unclear. In the next section, we turn to an analysis of some 'typical' replicators encountered on the net and elsewhere.

Replicators I: Chain Letters

Even before the existence of the web, the 'chain letter' was a widely known instance of a replicating message (Goodenough and Dawkins 1994). These letters shaded into various kinds of deliberate pyramid selling schemes, the best known being the disastrous 'Ponzi Scheme' which is believed to have exacerbated civil unrest in Albania. (It is an interesting issue whether such a scheme could have had such a dramatic effect outside a highly insular former communist country. The analogy with viral 'resistance' is obvious.) The basic idea behind these letters is that one sends a dollar, or some stamps, or a photograph to a certain number of people, and at some time in the future one is deluged with many instances of the same. (What differentiates a deliberate pyramid selling scheme is whether all copies of the letter involve sending something to the originator.) These letters encourage replication and 'repay' the efforts of duplication with promises of (spurious) reward. Brief reflection makes it clear that only a very few people in the pyramid can show a substantial net gain from the scheme and only at the expense of many losers, the system being closed. Legislation against pyramid selling and ease of falsification - one only has to participate once to realize that the flood of inward mail is not forthcoming - has resulted in these paper letters becoming widely known and unpopular.

What is interesting is that the chain letters which have survived, both on and off the net, are those which actually promise *less* tangible benefits, but also incur lower costs. Two well known examples are the so called 'Grapefruit of Love' and the request for business cards or postcards (accounts differ) to be sent to 'Craig Shergold'. In the first case, the message is a basically uplifting one, that someone who cares about you has sent the message on with positive thoughts, and that you should in turn pass it on to someone who you think needs it. (In many cases, as with jokes, this message is passed from friend to friend rather than via strangers. This increases its transmission rate as does the fact that the message will be sent more often to those most likely to appreciate it and perhaps in turn to other 'like-minded' individuals.) In the second case, the request is that cards should be sent to a UK cancer patient to cheer him up. More generally, chain letters have increasingly stressed intangibles like 'good luck' rather than more concrete rewards. They thus render themselves immune from obvious falsification and tap into a human tendency to 'superstition', spotting patterns where none exist. If I fail to pass on a chain letter and shortly afterwards something bad happens, I may connect the two events and be more susceptible in future. Replicators offering intangibles may also benefit from the fact that while only some of the population is interested in stamps, photographs and perhaps even free money, there are few who would not seek 'luck' or 'happiness' which they can interpret as they will.

Chain letters raise several issues that are also relevant to other classes of replicator. Firstly, they support the argument put forward by Dawkins that persistence is more important than many copies being made of the same message. Both of the above replicators typically contain no instructions about message duplication, thus lowering the minimum costs of compliance, but they will continue to persist as long as they generate *on average* at least one copy per recipient.

Another benefit of this strategy from the replicator perspective is that it partially conceals the nature of the message *as a replicator*. The emergent implications of a message like 'Please pass this on to a concerned friend' are far less clear than the implications of 'Duplicate this message ten times and send it to ten friends.' (As before, multiple duplication is *only one* evolved response to a population which has already been extensively immunized. We shall discuss others shortly.) Secondly, we can see that different sorts of replicator may be more or less effective at jumping from one medium to another. Because the net has very low costs of transmission, we would have expected certain forms of the standard chain letter to transfer to the web very readily, as has been observed with the Craig Shergold message, but not for replicators originating on the web to shift to other media. In fact, paper chain letters of the traditional form now seem to be all but extinct, perhaps for this reason. Thirdly, we offer the perhaps surprising hypothesis that chain letters offering less obvious personal benefits may actually survive better. Apart from the points already made about falsification and generality of interest, altruistic replicators are also less likely to produce discouraging responses from third parties. Not only did chain letters themselves become unpopular, but, to a lesser extent, so did people who passed them on. This applied not only to people who passed them on knowingly, but also reflected badly on the naiveté of those who passed them on *unknowingly*. Since a highly negative response from a third party will not only discourage an individual from passing on a particular chain letter, but *anything* they subsequently recognize as such, replicators have an 'incentive' to avoid producing these responses and also to avoid identifying themselves. (A really extreme response may even take the critic 'out of circuit' altogether with regard to all those observing the outburst thus breaking up the transmission network.) This brings us on to the final point, which is that there is no consensus on the valuation of replicating messages. Certain replicators, like computer viruses, do concrete damage and are widely disapproved, while others have been reputed to fill up computer memory or slow down transmission of 'more useful' messages. (It would be interesting to know if these justifications are themselves urban legends.) By contrast, disapproval of certain replicators like lists of jokes - barring cases where they are sent to people who just don't like them - seems to depend entirely on their recognition *as* replicators which are regarded as a 'waste of time' or 'nuisance'. Perhaps some people resent being taken advantage of by pieces of text? This paper thus tries to remain neutral about whether messages of different kinds *should* replicate and merely concentrate on how they do it.

Replicators II: Virus Warnings

So far the discussion has applied equally well to paper replicators and to those variants which have found their way onto the Internet. Now we turn to replicators which seem particularly suited to the distinctive properties of the virtual world. In doing so, we hope to learn something about those properties. Text 1 is a well developed instance of the standard warning message about the 'Good Times' (sometimes 'Good News') virus. This is a very robust class of replicating message that has been circulating on the net for at least three years under a variety of different names (Join The Crew, xxx-1, Win a Holiday, Penpal Greetings, Deyeendra).

Please take note of this internet virus.

There is computer a virus that is being sent across the Internet. If you receive an E-mail message with the subject line "Good Times", DO NOT read the message. DELETE it immediately. Some miscreant is sending email under the title "Good Times" nationwide, if you get anything like this, DON'T DOWN LOAD THE FILE!!!! It has a virus that rewrites your hard drive, obliterating anything on it. Please be careful and forward this mail to anyone you care about.

The FCC released a warning last Wednesday concerning a matter of major importance to any regular user of the Internet. Apparently a new computer virus has been engineered by a user of AMERICA ON LINE that is unparalleled in its destructive capability. Other more well-known viruses such as "Stoned", "Airwolf" and "Michaelangelo" pale in comparison to the prospects of this newest creation by a warped mentality. What makes this virus so terrifying, said the FCC, is the fact that no program needs to be exchanged for a new computer to be infected. It can be spread through existing the email systems of the Internet.

Once a computer is infected, one of several things can happen. If the computer contains a hard drive, that will most likely be destroyed. If the program is not stopped, the computer's processor will be placed in an the nth-complexity infinite binary loop-which can severely damage the processor if left running that way too long.

Unfortunately, most novice computer users will not realize what is happening until it is far too late. Luckily there is one sure means of detecting what is now know as the "Good Times" virus. It always travels to new computers the same way in a text email message with the subject line reading "Good Times". Avoiding infection is easy once the file has been received simply by NOT READING IT!. The act of loading the file into the mail server's ASCII buffer causes the "Good Times" mainline program to initialize and execute.

The program is highly intelligent. It will send copies of itself to everyone whose email address is contained in a receive-mail file or a sent-mail file, if it can find one. It will then proceed to trash the computer it is running on.

The bottom line is: If you receive a file with the subject line "Good Times", delete it immediately! Do not read it! Rest assured that whoever's name was on the "From" line was surely struck by the virus. Warn your friends and local system users of this newest threat to the Internet! It could save them a lot of time and money.

DO NOT DOWNLOAD ANY FILE NAMES PKZIP300 REGARDLESS OF THE EXTENSION

We work closely with the military and received this message from a reliable source in DC this morning. A NEW Trojan Horse Virus has emerged on the Internet with the name PKZIP300.ZIP, so named as to give the impression that this file is a new version of the PKZIP software used to "ZIP" (compress) files. DO NOT DOWNLOAD this file under any circumstances!!! If you install or expand this file, the virus WILL wipe your hard drive clean and affect modems at 14.4 and higher. This is an extremely destructive virus and there is NOT yet a way of cleaning up this one.

REPEAT: DO NOT DOWNLOAD ANY FILE NAMES PKZIP300 REGARDLESS OF THE EXTENSION.

Text 1. A Particularly Horrible Virus Warning

This message displays a number of interesting features:

Essential Components of a Replicator: Replicators appear to have three essential components. The first is some sort of content, in this case, a warning about the viruses 'Good News' and 'PKZIP300'. The second component is an attempt to *warrant* the content of the message thus motivating belief in the reader. The third component is a separate motivation to transmit and/or multiply the message. In this example and those that follow, warranting text is marked in green and motivations to replicate in blue.

Non Falsifiability and Self-Concealment: It has already been mentioned that replicators may be more effective if they offer benefits that are less tangible since they may benefit both from human 'superstition' and the difficulty of effective falsification. This class of replicators is particularly interesting in this respect because it is the *warning* and not the virus itself that constitutes the replicator. In fact, as far as anyone can establish, there is no virus corresponding to any replicators in this class. Thus this replicator survives by eluding conclusive falsification and it does this by making use of a nonexistent referent. Although the message can be disregarded for technical reasons, these will not be effective in preventing non-technical users from transmitting it. This is particularly the case because, for reason discussed in Woolgar and Russell (1990), users are rather inclined to believe in computer viruses as just 'punishment' for electronic promiscuity. This replicator also actively discourages falsification by claiming that reading the infected message is precisely the way that the virus is spread. Thus anybody receiving an email with one of the 'threatening' titles will have a strong incentive not to investigate the message itself. This gives rise to another property of this class of replicators which is that they are frequently renamed, thus concealing themselves and extending their lifespans. Although all these messages are functionally equivalent, a person who has already been affected by xxx-1 may not spot the similarity with Good News particularly in the face of other minor variations occurring in transmission. Interestingly, this renaming may also foster the illusion that there are always new viruses cropping up and this may maintain willingness to pass on all messages in this class.

Technical Incoherence and Implausibility: The pieces of text marked in red and pink suggest that this replicator is intended to be transmitted by those who are relatively technically incompetent. Such novices form an increasing proportion of those on-line and are thus an effective vector. The message makes no distinction between an email message in plain text, a file (perhaps an attachment), a program and a virus as a component of a file or program and the discussion of the effects of the virus maintains this confusion. Some of the warnings are either meaningless - the delightful and sinister sounding 'nth-complexity infinite binary loop' - or implausible. Most operating systems and email programs simply do not support programs or macros that would allow the hard drive to be reformatted or search the mailboxes to compile lists of addresses. (The nearest we have so far to a virus that can cross platforms or affect machines with different operating systems are various kinds of macro viruses. However, these are similarly limited by the functionality of the application from within which they operate.) Finally, it is not at all clear what a virus program could do to a modem and the message is wise not to say!

Structural Incoherence: In general, the form of all these messages is rather strange, with repetitions, changes of tack, awkward constructions and inconsistencies suggesting that they have been augmented and modified repeatedly. Subjectively, the style is far worse than and different from that of a typical 'designed' email message with a single author. Although we have

not yet discussed the extent to which these messages may be deliberately designed, it appears that they continue to change and evolve after they have been 'released' in ways that were unforeseen by the original designer. To this extent, evolution and design are not incompatible as understandings of the spread of replicating messages. (More generally, replicators are subject to evolution to the extent that their implications are not foreseen. Even the most cunning designer of replicators is unlikely to be aware of all the ramifications of a given text so it will still be subjected to some selection pressure.) The replicator in Text 1 actually consists of two separate warnings that have become grafted together. The PKZIP warning is much more coherent than the other and more likely to be based on 'fact', but it is not clear why the two messages are traveling together since they refer to completely different infections. (In biology, there is a concept of 'evolutionary piggybacking'; one gene may continue to be associated with another provided it causes no harm. In this case, of course, two warnings may actually be more impressive and effective than one.) In this case, one can even speculate on where the two messages are joined, using knowledge of the postulated structure of a replicator. It seems likely that the sentence which begins 'Warn your friends...' was once a separate paragraph, since without it, the PKZIP part of the message which follows lacks an exhortation to reproduce and is thus 'incomplete'.

Warranting and Motivation to Propagate: These can be seen as two stages in getting the replicator transmitted. The first is that the content of the message should be believed. The second is that, given this belief, it should seem like an appropriate thing to pass the message on. Warrants internal to the message are usually provided both directly, using references to 'authorities' like the FCC (US Federal Communications Commission) or 'the military' (perhaps surprisingly) and indirectly, by adopting a quasi-technical tone that is a strange mixture of bulletin and anecdote. (In Text 2 below, for example, the writer of the message is supposed to know all the bad things that happened to the victim, even down to the header of the damaging file, but at the same time they can provide no better identification than 'someone'. Urban legends often provide this strange mixture of detail and vagueness.) The motivation to transmit is almost invariably couched in altruistic terms, urging the reader to pass the message on to friends or colleagues, thus enhancing its external warrant as coming from someone known to the next recipient.

Text 2 is another example of a replicator of the same class which shares almost no genetic material with Text 1 although it conveys a very similar message. (One possibility for the generation of new variants is that stories warning of viruses may also be told 'offline' with individuals then retelling the story into an email 'from scratch' as far as they recall it. One would expect the technical details to suffer particularly badly from this process, but it will be hard to study it.) It has some interesting additional features. Firstly, it has an external warrant from Professor Smith (name altered for confidentiality) who may or may not exist and have passed the message on in good faith. More generally, the headers of these messages, showing that they have been extensively passed on, may also act to reinforce their authenticity though they can be faked relatively easily. Secondly, this replicator conflates at least four warnings, suggesting that composite messages are more effective. Thirdly, there is a new twist to the ability of replicators to avoid falsification. Even with the dire threats of infection if one reads messages with the 'hazardous' titles, it may still occur to people that they don't actually seem to be getting any actual messages only the warnings. A virus purportedly called 'Returned or Unable to Deliver' gains effectiveness because all users, especially novices, will send messages that 'bounce' and

thus generate their own spurious confirmations of the existence of this replicator. If a novice sees a virus warning before reading one of these bounce messages, they may forever after see such messages as evidence of the virus being so effectively discouraged from checking. Finally, there is also a new twist on the exhortation to duplicate which is that this is '... an [sic] new virus ...' which '... not many people know about ...' Such additions seem to rely on a general inability to perceive the emergent implications of receiving replicating message copies personally. It is highly unlikely that one will really be among the first to receive such a message and the header may even directly refute that belief but there seems to be a tendency to take email at local 'face value'. (The same can be said of pyramid selling schemes where individuals fail to ask what will happen if everyone follows the same logic that they themselves have.)

The following came to Professor John Smith and he wanted to share this information with everyone as soon as possible. Please read it and be careful what you open.

-----Original Message-----

Sent: Wednesday, August 27, 1997 5:49 PM

Subject: Computer virus alert

WARNING!!! The following information was received yesterday from IBM. Please share it with anyone that might access the Internet.

There are several new viruses being sent via e-mail entitled "JOIN THE CREW," "PENPAL GREETINGS," and "RETURNED OR UNABLE TO DELIVER."

If you receive an e-mail entitled "JOIN THE CREW," DO NOT OPEN IT. It will erase EVERYTHING on your hard drive! Send this message out to as many people as you can ... this is a new virus, and not many people know about it yet.

There is a dangerous virus propagating across the Internet through an e-mail message entitled "PENPAL GREETINGS," DO NOT DOWNLOAD ANY MESSAGE ENTITLED "PENPAL GREETINGS." Delete it without reading it. This message appears to be a friendly letter asking you if you are interested in a penpal. By the time you read the letter, it is too late. The Trojan Horse virus will have already infected the boot sector of your hard drive, destroying all of the data present. It is a self-replicating virus. Once the message is read, it will AUTOMATICALLY forward itself to anyone whose e-mail address is present in YOUR mailbox! This virus will destroy your hard drive and holds the potential to destroy the hard drive of anyone whose mail is in your in-box, and anyone whose mail is in their in-box, and so on, and so on. If this virus keeps getting passed, it has the potential to do a great deal of damage to computer networks worldwide!!!

DO NOT open or even look at any mail that is entitled "Returned or Unable to Deliver." This virus will attach itself to your computer components and render them useless. Immediately delete any mail items that say this. AOL has said this is a very dangerous virus, and there is NO remedy for it at this time.

Please forward this message to all of your on-line friends. ASAP.
Here is another virus notice.

Subject: Virus Warning
IMPORTANT!!!!

It is essential that this problem be reconciled as soon as possible.

A few hours ago, Someone opened an E-mail that had the subject heading of ao4free.com

Within seconds of opening it, a window appeared and began to display all files that were being deleted ... The user immediately shut down the computer, but it was too late.

This virus wiped all out. It ate the Anti-Virus Software that comes with the Windows '95 Program along with F-Prot AVS. Neither was able to detect it. Please be careful and send this to as many people as possible, so maybe this new virus can be eliminated.

Please pass this on, to anyone you know.

----- End Forwarded Message -----

Text 2. Another Horrible Virus Warning

In the next section, we turn to evolved 'responses' to replicators which can be seen as immunizing the population and reducing further transmission.

Replicators III: Immunization Responses

In this section, we consider the evolved responses to particularly 'irritating' replicators. One difficulty is that there is relatively little permanence to newsgroup postings and individual emails so these will not provide long term immunity. This is also true because the numbers of web and net users is continuously growing as is the proportion of novices. Although there are many web pages devoted to debunking common hoax messages, there are many more people using email than have web access and the same applies to the possession of the relevant skills. How have immunizing replicators co-evolved to compete with the original replicators? Texts 3 and 4 provide two examples. Because they are emails, they affect the same constituency that is transmitting the replicators and will continue to propagate in the same way. Interestingly, neither message *relies* on exhortations to transmit although the second makes these exhortations in an obviously ironic way. Instead, transmission appears to take place through a combination of intrinsic humor and satirizing the pre-existing replicators. We would expect these immunizers to die out without a steady stream of the original replicators to feed on.

***** Badtimes Virus Alert *****

If you receive an e-mail with a subject of "Badtimes", delete it immediately WITHOUT reading it.

This is the most dangerous eMail virus yet. It will re-write your hard drive. Not only that, but it will scramble any disks that are even close to your computer.

It will recalibrate your refrigerator's coolness setting so all your icecream goes melty.

It will demagnetize the strips on all your credit cards, screw up the tracking

on your VCR and use subspace field harmonics to scratch any CD's you try to play.
 It will give your ex-boyfriend/girlfriend your new phone number.
 It will mix Kool-aid into your fishtank. It will drink all your beer and leave its socks out on the coffee table when there's company coming over.
 It will put a dead kitten in the back pocket of your good suit pants and hide your car keys when you are late for work.
 Badtimes will make you fall in love with a penguin. It will give you nightmares about circus midgets. It will pour sugar in your gas tank and shave off both your eyebrows while dating your current boyfriend/girlfriend behind your back and billing the dinner and hotel room to your Visa card.
 It will seduce your grandmother. It does not matter if she is dead, such is the power of Badtimes, it reaches out beyond the grave to sully those things we hold most dear.
 It moves your car randomly around parking lots so you can't find it. It will kick your dog. It will leave libidinous messages on your boss's voicemail in your voice! It is insidious and subtle. It is dangerous and terrifying to behold. It is also a rather interesting shade of mauve.
 Badtimes will give you Dutch Elm disease. It will leave the toilet seat up. It will make a batch of Methamphetamine in your bathtub and then leave bacon cooking on the stove while it goes out to chase grade-schoolers with your new snowblower.
 These are just a few signs ... Just be very careful!

Text 3. Badtimes Immunizer

Rather than a dry warning about specific replicators which would date rapidly, Badtimes satirizes the tone and content of the whole class of replicators and makes claims that are so self-evidently ridiculous that they may provoke skepticism about similar claims couched in more technical terms. Compare the 'subspace field harmonics' in Badtimes with the 'nth-complexity infinite binary loop' in the Good News message. Again, it is not clear whether what we should assume about the amount of deliberation that goes into these immunizers. It may be that some or all of them were rationally 'constructed' with the specific intention of reducing the transmission of replicators, or that they were created simply as a joke that has turned out to serve that 'purpose'. This kind of study illustrates the problems of relating intentions to consequences (Merton 1936).

 WARNING, CAUTION, DANGER, AND BEWARE!
 Gullibility Virus Spreading over the Internet!

 WASHINGTON, D.C.--The Institute for the Investigation of Irregular Internet Phenomena announced today that many Internet users are becoming infected by a new virus that causes them to believe without question every groundless story, legend, and dire warning that shows up in their inbox or on their browser. The Gullibility Virus, as it is called, apparently makes people believe and forward copies of silly hoaxes relating to cookie recipes, email

viruses, taxes on modems, and get-rich-quick schemes.

"These are not just readers of tabloids or people who buy lottery tickets based on fortune cookie numbers", a spokesman said. "Most are otherwise normal people, who would laugh at the same stories if told to them by a stranger on a street corner". However, once these same people become infected with the Gullibility Virus, they believe anything they read on the Internet.

"My immunity to tall tales and bizarre claims is all gone", reported one weeping victim. "I believe every warning message and sick child story my friends forward to me, even though most of the messages are anonymous." Another victim, now in remission, added, "When I first heard about Good Times, I just accepted it without question. After all, there were dozens of other recipients on the mail header, so I thought the virus must be true". It was a long time, the victim said, before she could stand up at a Hoaxees Anonymous meeting and state, "My name is Jane, and I've been hoaxed". Now, however, she is spreading the word. "Challenge and check whatever you read," she says.

Internet users are urged to examine themselves for symptoms of the virus, which include the following:

- The willingness to believe improbable stories without thinking.
- The urge to forward multiple copies of such stories to others.
- A lack of desire to take three minutes to check to see if a story is true.

T. C. is an example of someone recently infected. He told one reporter, "I read on the Net that the major ingredient in almost all shampoos makes your hair fall out, so I've stopped using shampoo". When told about the Gullibility Virus, T. C. said he would stop reading email, so that he would not become infected.

Anyone with symptoms like these is urged to seek help immediately. Experts recommend that at the first feelings of gullibility, Internet users rush to their favorite search engine and look up the item tempting them to thoughtless credence. Most hoaxes, legends, and tall tales have been widely discussed and exposed by the Internet community.

This message is so important, we're sending it anonymously! Forward it to all your friends right away! Don't think about it! This is not a chain letter! This story is true! Don't check it out! This story is so timely, there is no date on it! This story is so important, we're using lots of exclamation points! Lots!! For every message you forward to some unsuspecting person, the Home for the Hopelessly Gullible will donate ten cents to itself. (If you wonder how the Home will know you are forwarding these messages all over creation, you're obviously thinking too much.)

Text 4. Gullibility Virus Immunizer

The Gullibility Virus also satirizes the standard form and content of a replicating message rather closely - thus increasing its effectiveness - but at the same time highlights and makes explicit the

sort of 'tricks' used by replicators to ensure their propagation. In addition, it provides motivation, through ridicule, to avoid being associated with the victims described, even though they are obviously fictitious. Notice also that the three virus 'symptoms' described correspond exactly with the essential components of a replicator postulated in this paper: content - 'A lack of desire to take three minutes to check to see if a story is true' - assent - 'The willingness to believe improbable stories without thinking' - and reproduction - 'The urge to forward multiple copies of such stories to others.' There is not room to pursue the analysis of co-evolution in this paper, but the point of this section is to draw attention to the fact that the analogy with biological evolution is not a 'shallow' one in that it deals not only with the evolution of simple replicators, but also with more sophisticated processes like symbiosis (where the survival of the immunizers depends on the survival of replicators) and co-evolution. Co-evolution is the process by which the nature of the immunizers continues to change to take account of the nature of the replicators and vice versa (Thompson 1994).

Conclusions and Future Research

In a single paper, it has not been possible to do more than introduce a memic analysis of messages on the web and net while attempting to sketch out a few of the implications. However, even this cursory analysis suggests that it may be useful to take a memic view of messages as manipulating their senders rather than vice versa. This is particularly the case where the relations between intentions and outcomes are not straightforward. There are four main areas in which the ideas here can be developed further:

Qualitative Analysis: Although I have analyzed a few replicator texts in a rather simplistic way, these texts and the dialogues about the correctness (or otherwise) of their transmission will bear considerable more detailed investigation from the perspective of Conversation Analysis, particularly making use of a much larger sample and using rigorous Qualitative Data Analysis. In particular, how do these messages do the task of getting transmitted and how do individuals argue for and against their transmission? What evidence do they bring to bear when the structure of the replicators actually seems to discourage falsification? Conversation Analysis proceeds from a Social Constructionist perspective which emphasizes the importance of competing accounts rather than the existence of objective facts of the matter. Regardless of whether this view is a correct representation of social processes - which of course one can only assert from a **non** Social Constructionist perspective - or an essential precondition to the use of CA, it is still the case that discussion of messages about potentially nonexistent viruses comes as close to a paradigm case for CA as it is possible to get. There really is nothing beyond the text of interaction to refer to.

Quantitative Analysis: So far, the claims that certain features of the replicator help or hinder its transmission have been very much subjective. This discussion needs to be followed up by the collection of a very much larger and more representative sample of instances from the web and net and attempts both to record the spread of different replicators over time and to demonstrate the evolution of variants for a single replicator.

Experimental Analysis: One very effective way to investigate the spread of replicators would be to deliberately design and release a replicator which combined the best insights about

effective transmission with ease of subsequent tracing. (There are also other experimental possibilities like an online questionnaire about beliefs and attitudes connected to replicators.) Ironically, too much detailed public discussion of this tracer might lower its effectiveness, but it is worth pointing out here that such an action raises ethical issues both because it contravenes the prevailing culture of the web and net in spreading unsolicited messages but also because it may involve deliberate deception of the researched. On the other hand, being 'open' about the function of the replicator, providing a contact email address on the message and so on might actually make the replicator far more effective. Indeed, it might become **too** effective so that the researcher was swamped with data. (This is in itself part of the urban legend of replicators, that the hospital mentioned in the 'Craig Shergold' replicator was swamped with cards.) Perhaps this message, or a summary of it, appended to a request for instances might itself constitute an effective replicator. I therefore ask, at this point, that anyone who receives messages of this kind or one they think they might be replicators to forward them to Edmund Chattoe with the header 'Replicator Instance' so I can filter them automatically. (I will doubtless make the amount of email I receive manageable by putting this request at the *end* of a rather long paper rather than at the beginning!) This raises another interesting issue which is that research in this area obviously contravenes the positivist agenda of distinguishing between researcher and researched. This paper, available as it is on the web, may well become part of the general debate on the transmission of replicators as was part of my intention in writing it. Conversely, in appealing for data, I will be changing the behavior of those who might transmit replicators, again not entirely unintentionally!

Simulation: Although there are techniques for both qualitative and quantitative analysis of existing and introduced replicators on the web, it is generally hard to synthesize these approaches. One possibility is to use computer simulation to build a model of an email network in which the mental states of transmitters or non-transmitters of messages are explicitly represented in simplified form so that the relation of intentions to replicator outcomes can also be studied. In such a model, some agents may themselves have belief sets about what will be credible and construct their messages accordingly, while others respond to messages 'unreflectingly' based only on what they themselves believe. Such simulations can also be used as investigative tools to suggest further hypotheses for testing on the web and net.

Finally, although this paper has chosen a research topic that is apparently very specific, it is possible that the insights gained will be far more general. How can marketers and advertisers produce replicators that will spread effectively by word of mouth? What are the memetic properties of ideologies and cultural norms that tend to ensure their propagation and persistence? What do replicators reveal about the distinctions between 'objective' and socially constructed facts? What is the relation between intentions and outcomes and between socially evolved and deliberate or rational behavior?

Acknowledgements

Perhaps unusually, this paper had a very specific genesis, which was the presentation and subsequent discussion of Woolgar and Russell (1990) at a conference in Bournemouth. I can say

that without hearing that paper, this one would never have been written and I am very grateful to Steve Woolgar for provoking my interest in this topic.

Department of Sociology, University of Surrey, GU2 5XH.*

*Edmund Chattoe is Associate Director of **CRESS** (The Centre for Research on Simulation in the Social Sciences) based in the Department of Sociology at the University of Surrey. This Centre aims to promote computer simulation among social scientists by offering training, advice and information. His research interests include simulation techniques, processes of social evolution, the application of Artificial Intelligence and Cognitive Science to social science and modeling decision making which involves both "social" and "rational" components.*

PARASITE ECOLOGY AND THE EVOLUTION OF RELIGION

By

Ben Cullen

Dept of Archaeology and Palaeoecology
Queen's University of Belfast
BELFAST BT7 1NN
NORTHERN IRELAND

Abstract: It is argued that the blanket view of religion as a disease, advocated by Dawkins, is inconsistent with the principles of parasite ecology. These principles state that vertically transmitted parasites evolve towards benign, symbiotic states, while horizontally transmitted parasites increase their virulence. Most of the world's established religions are transmitted vertically, from parents to children, and are therefore expected to be benign towards their hosts. Yet, certain horizontally transmitted cults, such as the Aum Shinrikyo, seem to effectively exploit their hosts in a way similar to an infectious disease.

Foreword by the editor

On December 29, 1995, while preparing this paper for publication, Ben Cullen unexpectedly died, apparently from an arrhythmia of the heart. This paper was one of two wonderful presentations which he had given at the conference "Einstein Meets Magritte" the previous summer. The unfinished manuscript consisted basically of the text he had read aloud during his presentation, which means that it lacked the structure typical of texts meant for publication. Therefore, I have edited the manuscript by dividing it into paragraphs and sections, eliminating references to photographs projected during the presentation, adding an abstract and bibliography, and correcting various small errors.

Let me elaborate why I find it important for Ben's work to be brought to the attention of the public. An Australian born in 1964, Ben Cullen graduated from the University of Sydney in 1987, with a degree in Prehistoric Archeology. After a stay as Research Fellow at the University of Wales, Lampeter, he moved to the Queen's University of Belfast a few months before his death. He had just defended his PhD thesis in archeology, in which he developed his "Cultural Virus Theory" (Cullen, 1993, 1995c, 1996), a stimulating new model of the evolution of culture, reminiscent of, but distinct from, the memetics view proposed by Dawkins (1989).

I met him in 1992 in London at a conference, where we were both presenting models of cultural evolution. We were obviously on the same wave length and had several long discussions after the lectures. I was impressed by his sharp intellect and the depth of his knowledge and understanding. Afterwards, we kept in touch by exchanging papers. Just a few weeks before his death, he sent me a preprint (Cullen, 1995) which he asked me to "really read, not like some others", which I interpreted to mean that many people misinterpret his ideas. There does not seem to be much danger of misinterpretation with the following paper, which is a jewel of clarity and simplicity.

Francis Heylighen

Introduction

There has been much recent publicity of the idea of religion and chain letters being diseases of the mind, or human information parasites as they are sometimes termed. Prominent amongst these have been pieces by the biologist Richard Dawkins in the London press, and also a piece about the St. Jude Chain Letter in a letter published recently in the leading scientific journal *Nature*. (Goodenough & Dawkins, 1994). Headlines such as the one about the 'St Jude' mind virus have not excited a great deal of controversy, presumably because few people publicly identify with chain letters.

However, other headlines, such as "Is Religion Just A Disease?" in the Daily Telegraph (Dawkins, 1993b), have excited a great deal of vociferous debate, and pricked many egos. Richard Dawkins's view of religion (1993a,b) as a disease not surprisingly offended members of the Church of England, and various bishops wrote pieces condemning both Dawkins and his view. But most objections to the "religion as a disease" idea have come from the Church acting in self-defense, guarding its cultural capital so to speak. Most defenses have come from theologians who submit the general idea that Dawkins is discussing spiritual matters beyond his understanding, a predictable theologian response. Very few objections have come from the sciences, human or otherwise. Few articles have explicitly disputed the scientific credentials of the Dawkins view, or the neo-Darwinian logic behind it.

In this paper I intend to go against this trend, and argue against the "religion as a disease" position, on the grounds that Dawkins has not manipulated neo-Darwinian logic consistently. In other words, I will argue that Dawkins has erected a highly personal view of religion which is in complete conflict with both his own selfish gene theories (Dawkins, 1989), and a growing body of parasite research.

Principles of Parasite Ecology

Let me enumerate the basic principles emerging in recent parasite ecology, the rules which the Dawkins view of religion are in direct conflict with, yet also the rules which Dawkins himself helped to articulate.

The first rule is that *vertically transmitted* parasites, namely, those that tend to pass from parent to child, evolve toward decreasing virulence, ultimately approaching benign or symbiotic configurations. Vertically transmitted parasites find themselves in the same sequence of bodies as the genes of their hosts, generation after generation, and the two therefore share a common future. They are in the same evolutionary boat, so to speak, and if the boat sinks, both parties drown.

One classic example of this type of relationship is that between wood-boring ambrosia beetles and bacteria, an example which Dawkins has featured in discussions of this nature. The bacteria are entirely dependent upon the beetles for food and shelter, and live their entire lives inside beetle tissue, being carried into the next generation inside the eggs which the females lay. This route to the future, however, ensures that they pass from each parent beetle to the beetle's offspring, and they are, therefore, vertically transmitted. Thus the rule would predict that these

bacteria should be symbiotic, and indeed they are, as without them the beetles would be unable to reproduce. This is because male beetles can only develop from eggs in which the bacteria are present. Without the bacteria the beetles would be a race of female individuals who could only reproduce through sexual reproduction, a difficult situation at the best of times.

This general rule linking symbiosis with long term host/parasite cohabitation and vertical transmission also finds support elsewhere, particularly in the field of "Darwinian medicine" (Nesse & Williams, 1995), and in the work of researchers such as Paul Ewald (1990, 1995). For instance, it has been shown that new and less virulent strains of the AIDS virus are proving more successful in human populations where condoms are frequently used, and where viruses therefore have to spend longer periods of time in each host (Ewald, 1994).

Rule number 2 is simply the reverse of Rule number 1. Disease is often connected to *horizontal modes of transmission*, where parasites are transmitted indiscriminately with respect to host relationships. Horizontally transmitted parasites are as likely to be passed on between families as within families. Parasites of this kind tend to evolve toward a typical "disease" configuration. The presence of the parasite significantly alters the host body or behavior in such a way as to improve the parasite's chances of reproduction, and decrease that of the host. Curiously, this may involve enhancing the host's chances of survival, while preventing its reproduction, in an attempt to produce a thriving parasite factory. Some barnacles, for example, parasitize crabs by targeting the crab's sex organs first, and the vital organs last, so maintaining a living resource for the parasite for as long as possible.

One of the most spectacular parasites of all is not an animal, but a plant which hunts other plants. It too is horizontally transmitted, and conforms to the rule. The corpse flower, or *Rafflesia*, is a family of plants so called because many of them exude a smell of rotting meat, mimicking the smell, colour and texture of a corpse. At 30 to 40 inches or about 1 metre across, it is the largest known single flower, and one of the most extraordinary predators of the plant world. It is an inhabitant of the rainforests of Borneo and Sumatra. The corpse flower has no leaves, no stem, no roots or trunk. It actually lives inside the tissues of another plant, one of the many vines which grow so abundantly in the rainforest canopy, as a net of tiny threads. How it actually gets inside these vines is not known. Thus the stem from which this truly monstrous flower grows does not belong to the flower, but to *rafflesia's* victim. Once the parasitic flower grows to its full size, the host vine has usually collapsed into the leaf litter of the forest, and is hidden from view.

The *corpse flower* is an excellent example of a predator which stalks its prey from within, biding its time in the body of the host vine, before leaping to new victims by means of its extraordinary flowers. To move through the forest, it enlists the help of tree shrews (small arboreal mammals) and insects. Viewed from the inside, the corpse flower is even more remarkable. Exuding a powerful aroma similar to a pile of fish after three days in the hot sun, it not surprisingly attracts flies. The flies crawl down to the sex organs, and there they are daubed with pollen which may then be carried to female flowers. The female flowers produce seeds which are then transported by small tree shrews to new vine hosts, elsewhere in the rainforest.

Religions as Parasites

Rafflesia is particularly relevant to the "religion as a disease" debate because it represents a rare example of a large predator that inhabits the bodies of its prey. It allows us to begin to imagine how an organisation such as a religion could be seen as a life form which inhabits the bodies of people, in the same way that rafflesia inhabits the bodies of rainforest vines. Anatomically, the corpse flower and cultural life forms have much more in common than one might expect.

This is a representation of the anatomy of a religion and its material products, in this case the megalithic tombs of Neolithic western Europe (Cullen, 1994). The outer ring of structures represent megaliths, but they could just as well be churches, or mosques or cathedrals. The central structures of the religion are composed of people, which are represented by the figure in the bottom corner--a circle for a head and a monk's robe for the body. There is an outer ring of acolytes or novices, whose heads are represented by circles A, B, C, and D their bodies by a robe, and the actions they perform in service of the religion by arrows. Finally there is an inner circle of priests or clergy, whose heads are represented by circles 1, 2, 3, and 4, their bodies by robes, and their actions by arrows. The religion or cultural organism consists solely of the shaded black areas and their material products - the people involved in the organisation may perform many other roles in society, some of these roles might work against the religion. So this schematic diagram gives us some idea of what a cultural life form looks like.

Now, using the rules of parasite ecology discussed a little earlier, we can begin to predict which religions will evolve toward disease-like states, and which religions should evolve toward benign or symbiotic states. Vertically transmitted religions, like vertically transmitted viruses and other parasites, should evolve toward symbiotic or benign states. This immediately disqualifies most of the world's established religions from the "disease" scenario, because they are generally passed on from generation to generation within the family. Family dependent religious affiliation should therefore evolve toward benign or symbiotic configurations. Dawkins actually points out the vertically transmitted nature of religions, although he does not connect it to any prediction of symbiosis.

For the same reasons, we would expect the religions of small scale, kinship based societies, such as those of indigenous Australian cultures and their associated artistic traditions, to evolve toward symbiotic configurations. When a religion occupies of small community in which members of subsequent generations are of close genetic relationship to previous generations, a pathological religion would tend to plunge itself and its community into oblivion.

But this is not to say that there can be no such thing as a parasitic religion. However, if we are to find a truly pathological religion, we will have to look for examples where the pattern of transmission is horizontal, or essentially indiscriminate with respect to genetic relatedness of new recruits. Established world religions cannot be totally excluded from the picture, as while congregational membership may be essentially vertically transmitted, membership of the priesthood is not so rigid. Nor can the religions of kinship based communities be totally excluded, as kinship is often employed as a means of social categorisation for both strangers or newcomers and family alike. So called "fictive" kinship of this kind can and often does follow a

line of descent which does not conform to strict lines of genetic inheritance. So we might expect occasional parasitic forms of religion to arise in the established traditions.

But are there any more dramatic examples around? I think that we may not have to look too far. Religious cults would appear to be a good candidate. Chizuo Matsumoto, better known as Shoko Asahara, is the leader of the doomsday cult of Aum Shinrikyo or Way of the Divine Truth. The Way of the Divine Truth organization was apparently responsible for the recent nerve gas attack on the Tokyo subway system.

The Aum Shinrikyo doomsday cult undoubtedly follows a horizontal pattern of transmission, selecting its recruits more for what they can do for the cult than for their relatedness to existing members. The rate at which it acquired members, many of them outside Japan, is testimony to the non-vertical nature of its reproduction. In the space of a decade or so, the cult acquired some 30,000 members in Russia, presumably none of them related to Asahara himself. Within Japan the cult boasted a surprising number of members from all walks of life. Asahara carefully chose the most talented individuals for his priests, recruiting lawyers, scientists, chemists and engineers. With so many thousands of members in such a short time, it is clear that the cult did not rely on the fecundity of its members for its expansion. Clearly, then, the Aum Shinrikyo doomsday cult was a horizontally transmitted phenomenon.

Parasite ecology, then, would predict that it would exploit some or all of its members. Is there any evidence of this? It would appear that there was. One recruit had to provide a list of her assets and promise that they would be passed over to the cult on her death. The most privileged were allowed to drink Asahara's blood or semen, but actually had to pay an incredible 74,000 pounds for the pleasure. Cult members received very little in return for these immense financial contributions to the cult. Apart from the lucky few allowed to drink a little blood or semen, they received dormitory or boarding school style accommodation, and two meager vegetarian meals per day. The 53 children moved from the cult's commune proved to be suffering from severe malnutrition, while Asahara himself lived in luxury. An older recruit related how he was told to drink several gallons of water and vomit them as part of his training. So it would seem that the Aum Shinrikyo doomsday cult of Shoko Asahara does indeed conform to principles of parasite ecology.

In conclusion, then, it would appear that the blanket view of religion as a disease, as advocated by Dawkins (1993a,b), is not consistent with recent research into the nature of parasite evolution. Many religions are being vertically transmitted or family dependent, and we would therefore expect them to evolve toward symbiosis or at least benignness. As Dawkins has remarked, it is an extraordinary fact that if we adhere to a faith at all, it is overwhelmingly likely to be the same as that of our parents. This simple fact ought to ensure that if a religion which followed this pattern of transmission ruthlessly exploited its congregation, it would eventually plunge both itself and its people into extinction.

CHAPTER 11 FROM “THE SELFISH GENE”

By
Richard Dawkins

First published 1976; 1989 edition: Oxford University Press, ISBN 0-19-286092-5 (paperback): the best short introduction to, and the text that kicked off, the new science of **MEMETICS**, (and, also, the text where Dawkins coined the term `meme').

The following key paragraph of this chapter may perhaps serve as an **abstract**:

Examples of memes are tunes, ideas, catch-phrases, clothes fashions, ways of making pots or of building arches. Just as genes propagate themselves in the gene pool by leaping from body to body via sperms or eggs, so memes propagate themselves in the meme pool by leaping from brain to brain via a process which, in the broad sense, can be called imitation. If a scientist hears, or reads about, a good idea, he passed it on to his colleagues and students. He mentions it in his articles and his lectures. If the idea catches on, it can be said to propagate itself, spreading from brain to brain. As my colleague N.K. Humphrey neatly summed up an earlier draft of this chapter: `... memes should be regarded as living structures, not just metaphorically but technically.(3) When you plant a fertile meme in my mind you literally parasitize my brain, turning it into a vehicle for the meme's propagation in just the way that a virus may parasitize the genetic mechanism of a host cell. And this isn't just a way of talking -- the meme for, say, "belief in life after death" is actually realized physically, millions of times over, as a structure in the nervous systems of individual men the world over.'

The notes (1), (2) ... are from the 1989 edition. Highlights ** and text in square brackets are not original.

11. Memes: the new replicators

So far, I have not talked much about man in particular, though I have not deliberately excluded him either. Part of the reason I have used the term `survival machine' is that `animal' would have left out plants and, in some people's minds, humans. The arguments I have put forward should, prima facie, apply to any evolved being. If a species is to be excepted, it must be for good reasons. Are there any good reasons for supposing our own species to be unique? I believe the answer is yes.

Most of what is unusual about man can be summed up in one word: `culture'. I use the word not in its snobbish sense, but as a scientist uses it. Cultural transmission is analogous to genetic transmission in that, although basically conservative, it can give rise to a form of evolution. Geoffrey Chaucer could not hold a conversation with a modern Englishman, even though they are linked to each other by an unbroken chain of some twenty generations of Englishmen, each of whom could speak to his immediate neighbors in the chain as a son speaks to his father. Language seems to `evolve' by non-genetic means, and at a rate which is orders of magnitude faster than genetic evolution.

Cultural transmission is not unique to man. The best non-human example that I know has recently been described by P.F. Jenkins in the song of a bird called the saddleback which lives on islands off New Zealand. On the island where he worked there was a total repertoire of about nine distinct songs. Any given male sang only one or a few of these songs. The males could be classified into dialect groups. For example, one group of eight males with neighboring territories sang a particular song called the CC song. Other dialect groups sang different songs. Sometimes the members of a dialect group shared more than one distinct song. By comparing the songs of fathers and sons, Jenkins showed that song patterns were not inherited genetically. Each young male was likely to adopt songs from his territorial neighbors by imitation, in an analogous way to human language. During most of the time Jenkins was there, there was a fixed number of songs on the island, a kind of 'song pool' from which each young male drew his own small repertoire. But occasionally Jenkins was privileged to witness the 'invention' of a new song, which occurred by a mistake in the imitation of an old one. He writes: 'New song forms have been shown to arise variously by change of notes and the combination of parts of other existing songs ... The appearance of the new form was an abrupt event and the product was quite stable over a period of years. Further, in a number of cases the variant was transmitted accurately in its new form to younger recruits so that a recognizably coherent group of like singers developed.' Jenkins refers to the origins of new songs as 'cultural mutations'.

Song in the saddleback truly evolves by non-genetic means. There are other examples of cultural evolution in birds and monkeys, but not these are just interesting oddities. It is our own species that really shows what cultural evolution can do. Language is one example out of many. Fashions in dress and diet, ceremonies and customs, art and architecture, engineering and technology, all evolve in historical time in a way that looks like highly speeded up genetic evolution, but has really nothing to do with genetic evolution. As in genetic evolution though, the change may be progressive. There is a sense in which modern science is actually better than ancient science. Not only does our understanding of the universe change as the centuries go by: it improves. Admittedly the current burst of improvement dates back to the Renaissance, which was preceded by a dismal period of stagnation, in which European scientific culture was frozen at the level achieved by the Greeks. But, as we saw in chapter 5, genetic evolution too may proceed as a series of brief spurts between stable plateau.

The analogy between cultural and genetic evolution has frequently been pointed out, sometimes in the context of quite unnecessary mystical overtones. The analogy between scientific progress and genetic evolution by natural selection has been illuminated especially by Sir Karl Popper. I want to go even further into directions which are also being explored by, for example, the geneticist L.L. Cavalli-Sforza, the anthropologist F.T. Cloak, and the ethologist J.M. Cullen.

As an enthusiastic Darwinian, I have been dissatisfied with explanations that my fellow-enthusiasts have offered for human behavior. They have tried to look for 'biological advantages' in various attributes of human civilization. For example, tribal religion has been seen as a mechanism for solidifying group identity, valuable for a pack-hunting species whose individuals rely on cooperation to catch large and fast prey. Frequently the evolutionary preconception in terms of which such theories are framed is implicitly group-selectionist, but it is possible to rephrase the theories in terms of orthodox gene selection. Man may well have spent large portions of the last several million years living in small kin groups. Kin selection and selection

in favor of reciprocal altruism may have acted on human genes to produce many of our basic psychological attributes and tendencies. These ideas are plausible as far as they go, but I find that they do not begin to square up to the formidable challenge of explaining culture, cultural evolution, and the immense differences between human cultures around the world, from the utter selfishness of the Ik of Uganda, as described by Colin Turnbull, to the gentle altruism of Margaret Mead's Arapesh. I think we have got to start again and go right back to first principles. The argument I shall advance, surprising as it may seem coming from the author of the earlier chapters, is that, for an understanding of the evolution of modern man, we must begin by throwing out the gene as the sole basis of our ideas on evolution. I am an enthusiastic Darwinian, but, I think Darwinism is too big a theory to be confined to the narrow context of the gene. The gene will enter my thesis as an analogy, nothing more.

What, after all, is so special about genes? The answer is that they are replicators. The laws of physics are supposed to be true all over the accessible universe. Are there any principles of biology that are likely to have similar universal validity? When astronauts voyage to distant planets and look for life, they can expect to find creatures too strange and unearthly for us to imagine. But is there anything that must be true of all life, wherever it is found, and whatever the basis of its chemistry? If forms of life exist whose chemistry is based on silicon rather than carbon, or ammonia rather than water, if creatures are discovered that boil to death at -100 degrees centigrade, if a form of life is found that is not based on chemistry at all but on electronic reverberating circuits, will there still be any general principle that is true of all life? Obviously I do not know but, if I had to bet, I would put my money on one fundamental principle. This is the law that all life evolves by the differential survival of replicating entities. (1) The gene, the DNA molecule, happens to be the replicating entity that prevails on our planet. There may be others. If there are, provided certain other conditions are met, they will almost inevitably tend to become the basis for an evolutionary process.

But do we have to go to distant worlds to find other kinds of replicator and other, consequent, kinds of evolution? I think that a new kind of replicator has recently emerged on this very planet. It is staring us in the face. It is still in its infancy, still drifting clumsily about in its primeval soup, but already it is achieving evolutionary change at a rate that leaves the old gene panting far behind.

The new soup is the soup of human culture. We need a name for the new replicator, a noun that conveys the idea of a unit of cultural transmission, or a unit of *imitation*. 'Mimeme' comes from a suitable Greek root, but I want a monosyllable that sounds a bit like 'gene'. I hope my classicist friends will forgive me if I abbreviate mimeme to *meme*. (2) If it is any consolation, it could alternatively be thought of as being related to 'memory', or to the French word *même*. It should be pronounced to rhyme with 'cream'.

Examples of memes are tunes, ideas, catch-phrases, clothes fashions, ways of making pots or of building arches. Just as genes propagate themselves in the gene pool by leaping from body to body via sperms or eggs, so memes propagate themselves in the meme pool by leaping from brain to brain via a process which, in the broad sense, can be called imitation. If a scientist hears, or reads about, a good idea, he passed it on to his colleagues and students. He mentions it in his articles and his lectures. If the idea catches on, it can be said to propagate itself, spreading

from brain to brain. As my colleague N.K. Humphrey neatly summed up an earlier draft of this chapter: `... memes should be regarded as living structures, not just metaphorically but technically.(3) When you plant a fertile meme in my mind you literally parasitize my brain, turning it into a vehicle for the meme's propagation in just the way that a virus may parasitize the genetic mechanism of a host cell. And this isn't just a way of talking -- the meme for, say, "belief in life after death" is actually realized physically, millions of times over, as a structure in the nervous systems of individual men the world over.'

Consider the idea of God. We do not know how it arose in the meme pool. Probably it originated many times by independent `mutation'. In any case, it is very old indeed. How does it replicate itself? By the spoken and written word, aided by great music and great art. Why does it have such high survival value? Remember that `survival value' here does not mean value for a gene in a gene pool, but value for a meme in a meme pool. The question really means: What is it about the idea of a god that gives it its stability and penetrance in the cultural environment? The survival value of the god meme in the meme pool results from its great psychological appeal. It provides a superficially plausible answer to deep and troubling questions about existence. It suggests that injustices in this world may be rectified in the next. The `everlasting arms' hold out a cushion against our own inadequacies which, like a doctor's placebo, is none the less effective for being imaginary. These are some of the reasons why the idea of God is copied so readily by successive generations of individual brains. God exists, if only in the form of a meme with high survival value, or infective power, in the environment provided by human culture.

Some of my colleagues have suggested to me that this account of the survival value of the god meme begs the question. In the last analysis they wish always to go back to `biological advantage'. To them it is not good enough to say that the idea of a god has `great psychological appeal'. They want to know *why* it has great psychological appeal. Psychological appeal means appeal to brains, and brains are shaped by natural selection of genes in gene-pools. They want to find some way in which having a brain like that improves gene survival.

I have a lot of sympathy with this attitude, and I do not doubt that there are genetic advantages in our having brains of the kind we have. But nevertheless I think that these colleagues, if they look carefully at the fundamentals of their own assumptions, will find that they begging just as many questions as I am. Fundamentally, the reason why it is good policy for us to try to explain biological phenomena in terms of gene advantage is that genes are replicators. As soon as the primeval soup provided conditions in which molecules could make copies of themselves, the replicators themselves took over. For more than three thousand million years, DNA has been the only replicator worth talking about in the world. But it does not necessarily hold these monopoly rights for all time. Whenever conditions arise in which a new kind of replicator *can* make copies of itself, the new replicators *will* tend to take over, and start a new kind of evolution of their own. Once this new evolution begins, it will in no necessary sense be subservient to the old. The old gene-selected evolution, by making brains, provided the `soup' in which the first memes arose. Once self-copying memes had arisen, their own, much faster, kind of evolution took off. We biologists have assimilated the idea of genetic evolution so deeply that we tend to forget that it is only one of many possible kinds of evolution.

Imitation, in the broad sense, is how memes *can* replicate. But just as not all genes that can replicate do so successfully, so some memes are more successful in the meme-pool than others. This is the analogue of natural selection. I have mentioned particular examples of qualities that make for high survival value among memes. But in general they must be the same as those discussed for the replicators of Chapter 2: longevity, fecundity, and copying-fidelity. The longevity of any one copy of a meme is probably relatively unimportant, as it is for any one copy of a gene. The copy of the tune 'Auld Lang Syne' that exists in my brain will last only for the rest of my life. (4) The copy of the same tune that is printed in my volume of *The Scottish Student's Song Book* is unlikely to last much longer. But I expect there will be copies of the same tune on paper and in people's brains for centuries to come. As in the case of genes, fecundity is much more important than longevity of particular copies. If the meme is a scientific idea, its spread will depend on how acceptable it is to the population of individual scientists; a rough measure of its survival value could be obtained by counting the number of times it is referred to in successive years in scientific journals.(5) If it is a popular tune, its spread through the meme pool may be gauged by the number of people heard whistling it in the streets. If it is a style of women's shoe, the population memeticist may use sales statistics from shoe shops. Some memes, like some genes, achieve brilliant short-term success in spreading rapidly, but do not last long in the meme pool. Popular songs and stiletto heels are examples. Others, such as the Jewish religious laws, may continue to propagate themselves for thousands of years, usually because of the great potential permanence of written records.

This brings me to the third general quality of successful replicators: copying-fidelity. Here I must admit that I am on shaky ground. At first sight it looks as if memes are not high-fidelity replicators at all. Every time a scientist hears an idea and passes it on to somebody else, he is likely to change it somewhat. I have made no secret of my debt in the book to the ideas of R.L. Trivers. Yet I have not repeated them in his own words. I have twisted them round for my own purposes, changing the emphasis, blending them with ideas of my own and of other people. The memes are being passed on to you in altered form. This looks quite unlike the particulate, all-or-none quality of gene transmission. It looks as though meme transmission is subject to continuous mutation, and also to blending.

It is possible that this appearance of non-particulate is illusory and that the analogy with genes does not break down. After all, if we look at the inheritance of many genetic characters such as human height or skin-coloring, it does not look like the work of indivisible and unbendable genes. If a black and a white person mate, their children do not come out either black or white: they are intermediate. This does not mean the genes concerned are not particulate. It is just that there are so many of them concerned with skin color, each one having such a small effect, that they *seem* to blend. So far I have talked of memes as though it was obvious what a single unit-meme consisted of. But of course that is far from obvious. I have said a tune is one meme, but what about a symphony: how many memes is that? Is each movement one meme, each recognizable phrase of melody, each bar, each chord, or what?

I appeal to the same verbal trick as I used in Chapter 3. There I divided the 'gene complex' into large and small genetic units, and units within units. The 'gene' was defined, not in a rigid all-or-none way, but as a unit of convenience, a length of chromosome with just sufficient copying-fidelity to serve as a viable unit of natural selection. If a single phrase of Beethoven's ninth

symphony is sufficiently distinctive and memorable to be abstracted from the context of the whole symphony, and used as the call-sign of a maddeningly intrusive European broadcasting station, then to that extent it deserves to be called one meme. It has, incidentally, materially diminished my capacity to enjoy the original symphony.

Similarly, when we say that all biologists nowadays believe in Darwin's theory, we do not mean that every biologist has graven in his brain, an identical copy of the exact words of Charles Darwin himself. Each individual has his own way of interpreting Darwin's ideas. He probably learned them not from Darwin's own writings, but from more recent authors. Much of what Darwin said is, in detail, wrong. Darwin if he read this book would scarcely recognize his own theory in it, though I hope he would like the way I put it. Yet, in spite of all this, there is something, some essence of Darwinism, which is present in the head of every individual who understands the theory. If this were not so, then almost any statement about two people agreeing with each other would be meaningless. An 'idea-meme' might be defined as an entity that is capable of being transmitted from one brain to another. The meme of Darwin's theory is therefore that essential basis of the idea which is held in common by all brains that understand the theory. The *differences* in the ways that people represent the theory are then, by definition, not part of the meme. If Darwin's theory can be subdivided into components, such that some people believe component *A* but not component *B*, while others believe *B* but not *A*, then *A* and *B* should be regarded as separate memes. If almost everybody who believes in *A* also believes in *B* -- if the memes are closely 'linked' to use the genetic term -- then it is convenient to lump them together as one meme.

Let us pursue the analogy between memes and genes further. Throughout this book, I have emphasized that we must not think of genes as conscious, purposeful agents. Blind natural selection, however, makes them behave rather *as if* they were purposeful, and it has been convenient, as a shorthand, to refer to genes in the language of purpose. For example, when we say 'genes are trying to increase their numbers in future gene pools', what we really mean is 'those genes that behave in such a way as to increase their numbers in future gene pools tend to be the genes whose effects we see in the world'. Just as we have found it convenient to think of genes as active agents, working purposefully for their own survival, perhaps it might be convenient to think of memes in the same way. In neither case must we get mystical about it. In both cases the idea of purpose is only a metaphor, but we have already seen what a fruitful metaphor it is in the case of genes. We have even used words like 'selfish' and 'ruthless' of genes, knowing full well it is only a figure of speech. Can we, in exactly the same spirit, look for selfish or ruthless memes?

There is a problem here concerning the nature of competition. Where there is sexual reproduction, each gene is competing particularly with its own alleles -- rivals for the same chromosomal slot. Memes seem to have nothing equivalent to alleles. I suppose there is a trivial sense in which many ideas can be said to have 'opposites'. But in general memes resemble the early replicating molecules, floating chaotically free in the primeval soup, rather than modern genes in their neatly paired, chromosomal regiments. In what sense then are memes competing with each other? Should we expect them to be 'selfish' or 'ruthless', if they have no alleles? The answer is that we might, because there is a sense in which they must indulge in a kind of competition with each other.

Any user of a digital computer knows how precious computer time and memory storage space are. At many large computer centers they are literally costed in money; or each user may be allotted a ration of time, measured in seconds, and a ration of space, measured in 'words'. The computers in which memes live are human brains. (6) Time is possibly a more important limiting factor than storage space, and it is the subject of heavy competition. The human brain, and the body that it controls, cannot do more than one or a few things at once. If a meme is to dominate the attention of a human brain, it must do so at the expense of 'rival' memes. Other commodities for which memes compete are radio and television time, billboard space, newspaper column-inches, and library shelf-space.

In the case of genes, we saw in Chapter 3 that co-adapted gene complexes may arise in the gene pool. A large set of genes concerned with mimicry in butterflies became tightly linked together on the same chromosome, so tightly that they can be treated as one gene. In Chapter 5 we met the more sophisticated idea of the evolutionarily stable set of genes. Mutually suitable teeth, claws, guts, and sense organs evolved in carnivore gene pools, while a different stable set of characteristics emerged from herbivore gene pools. Has the god meme, say, become associated with any other particular memes, and does this association assist the survival of each of the participating memes? Perhaps we could regard an organized church, with its architecture, rituals, laws, music, art, and written tradition, as a co-adapted set of mutually-assisting memes.

To take a particular example, an aspect of doctrine that has been very effective in enforcing religious observance is the threat of hell fire. Many children and even some adults believe that they will suffer ghastly torments after death if they do not obey the priestly rules. This is a peculiarly nasty technique of persuasion, causing great psychological anguish throughout the middle ages and even today. But it is highly effective. It might almost have been planned deliberately by a Machiavellian priesthood trained in deep psychological indoctrination techniques. However, I doubt if the priests were that clever. Much more probably, unconscious memes have ensured their own survival by virtue of those same qualities of pseudo-ruthlessness that successful genes display. The idea of hell fire is, quite simply, *self perpetuating*, because of its own deep psychological impact. It has become linked with the god meme because the two reinforce each other, and assist each other's survival in the meme pool.

Another member of the religious meme complex is called faith. It means blind trust, in the absence of evidence, even in the teeth of evidence. The story of Doubting Thomas is told, not so that we shall admire Thomas, but so that we can admire the other apostles in comparison. Thomas demanded evidence. Nothing is more lethal for certain kinds of meme than a tendency to look for evidence. The other apostles, whose faith was so strong that they did not need evidence, are held up to us as worthy of imitation. The meme for blind faith secures its own perpetuation by the simple unconscious expedient of discouraging rational inquiry.

Blind faith can justify anything. (7) If a man believes in a different god, or even if he uses a different ritual for worshipping the same god, blind faith can decree that he should die -- on the cross, at the stake, skewered on a Crusader's sword, shot in a Beirut street, or blown up in a bar in Belfast. Memes for blind faith have their own ruthless ways of propagating themselves. This is true of patriotic and political as well as religious blind faith.

Memes and genes may often reinforce each other, but they sometimes come into opposition. For example, the habit of celibacy is presumably not inherited genetically. A gene for celibacy is doomed to failure in the gene pool, except under very special circumstances such as we find in the social insects. But still, a *meme* for celibacy can be successful in the meme pool. For example, suppose the success of a meme depends critically on how much time people spend in actively transmitting it to other people. Any time spent in doing other things than attempting to transmit the meme may be regarded as time wasted from the meme's point of view. The meme for celibacy is transmitted by priests to young boys who have not yet decided what they want to do with their lives. The medium of transmission is human influence of various kinds, the spoken and written word, personal example, and so on. Suppose, for the sake of argument, it happened to be the case that marriage weakened the power of a priest to influence his flock, say because it occupied a large proportion of his time and attention. This has, indeed, been advanced as an official reason for the enforcement of celibacy among priests. If this were the case, it could follow that the meme for celibacy could have greater survival value than the meme for marriage. Of course, exactly the opposite would be true for a *gene* for celibacy. If a priest is a survival machine for memes, celibacy is a useful attribute to build into him. Celibacy is just a minor partner in a large complex of mutually-assisting religious memes.

I conjecture that co-adapted meme-complexes evolve in the same kind of way as co-adapted gene-complexes. Selection favors memes that exploit their cultural environment to their own advantage. This cultural environment consists of other memes which are also being selected. The meme pool therefore comes to have the attributes of an evolutionarily stable set, which new memes find it hard to invade.

I have been a bit negative about memes, but they have their cheerful side as well. When we die there are two things we can leave behind us: genes and memes. We were built as gene machines, created to pass on our genes. But that aspect of us will be forgotten in three generations. Your child, even your grandchild, may bear a resemblance to you, perhaps in facial features, in a talent for music, in the color of her hair. But as each generation passes, the contribution of your genes is halved. It does not take long to reach negligible proportions. Our genes may be immortal but the *collection* of genes that is any one of us is bound to crumble away. Elizabeth II is a direct descendant of William the Conqueror. Yet it is quite probable that she bears not a single one of the old king's genes. We should not seek immortality in reproduction.

But if you contribute to the world's culture, if you have a good idea, compose a tune, invent a sparking plug, write a poem, it may live on, intact, long after your genes have dissolved in the common pool. Socrates may or may not have a gene or two alive in the world today, as G.C. Williams has remarked, but who cares? The meme-complexes of Socrates, Leonardo, Copernicus and Marconi are still going strong.

However speculative my development of the theory of memes may be, there is one serious point which I would like to emphasize once again. This is that when we look at the evolution of cultural traits and at their survival value, we must be clear *whose* survival we are talking about. Biologists, as we have seen, are accustomed to looking for advantages at the gene level (or the individual, the group, or the species level according to taste). What we have not previously

considered is that a cultural trait may have evolved in the way that it has, simply because it is *advantageous to itself*.

We do not have to look for conventional biological survival values of traits like religion, music, and ritual dancing though these may also be present. Once the genes have provided their survival machines with brains that are capable of rapid imitation, the memes will automatically take over. We do not even have to posit a genetic advantage in imitation, though that would certainly help. All that is necessary is that the brain should be *capable* of imitation: memes will then evolve that exploit the capacity to the full.

I now close the topic of the new replicators, and end the chapter on a note of qualified hope. One unique feature of man, which may or may not have evolved memically, is his capacity for conscious foresight. Selfish genes (and, if you allow the speculation of this chapter, memes too) have no foresight. They are unconscious, blind, replicators. The fact that they replicate, together with certain further conditions means, willy nilly, that they will tend towards the evolution of qualities which, in the special sense of this book, can be called selfish. A simple replicator, whether gene or meme, cannot be expected to forgo short-term selfish advantage even if it would really pay it, in the long term, to do so. We saw this in the chapter on aggression. Even though a `conspiracy of doves' would be better for *every single individual* than the evolutionarily stable strategy [=ESS], natural selection is bound to favor the ESS.

It is possible that yet another unique quality of man is a capacity for genuine, disinterested, true altruism. I hope so, but I am not going to argue the case one way or another, nor to speculate over its possible memic evolution. The point I am making now is that, even if we look on the dark side and assume that individual man is fundamentally selfish, our conscious foresight -- our capacity to simulate the future in imagination -- could save us from the worst selfish excesses of the blind replicators. We have at least the mental equipment to foster our long-term selfish interests rather than merely our short-term selfish interests. We can see the long-term benefits of participating in a `conspiracy of doves', and we can sit down together to discuss ways of making the conspiracy work. We have the power to defy the selfish genes of our birth and, if necessary, the selfish memes of our indoctrination. We can even discuss ways of deliberately cultivating and nurturing pure, disinterested altruism -- something that has no place in nature, something that has never existed before in the whole history of the world. We are built as gene machines and cultured as meme machines, but we have the power to turn against our own creators. We, alone on earth, can rebel against the tyranny of the selfish replicators. (8)

NOTES

(1) *I would put my money on one fundamental principle ... all life evolves by the differential survival of replicating entities.*

My wager that all life, everywhere in the universe, would turn out to have evolved by Darwinian means has now been spelled out and justified more fully in my paper `Universal Darwinism' and in the last chapter of *The Blind Watchmaker*. I show that all the alternatives to Darwinism that have ever been suggested are in principle incapable of doing the job of explaining the organized complexity of life. The argument is a general one, not based upon particular facts about life as

we know it. As such it has been criticized by scientists pedestrian enough to think that slaving over a hot test tube (or cold muddy boot) is the only method of discovery in science. One critic complained that my argument was 'philosophical', as though that was sufficient condemnation. Philosophical or not, the fact is that neither he nor anybody else has found any flaw in what I said. And 'in principle' arguments such as mine, far from being irrelevant to the real world, can be *more* powerful than arguments based on particular factual research. My reasoning, if it is correct, tells us something important about life everywhere in the universe. Laboratory and field research can tell us only about life as we have sampled it here.

(2) *Meme*

The word meme seems to be turning out to be a good meme. It is now quite widely used and in 1988 it joined the official list of words being considered for future editions of Oxford English Dictionaries. This makes me the more anxious to repeat that my designs on human culture were modest almost to vanishing point. My true ambitions -- and they are admittedly large -- lead in another direction entirely. I want to claim almost limitless power for slightly inaccurate self-replicating entities, once they arise anywhere in the universe. This is because they tend to become the basis for Darwinian selection which, given enough generations, cumulatively builds systems of great complexity. I believe that, given the right conditions, replicators automatically band together to create systems, or machines, that carry them around and work to favour their continued replication. The first ten chapters of *The Selfish Gene* had concentrated exclusively on one kind of replicator, the gene. In discussing memes in the final chapter I was trying to make the case for replicators in general, and to show that genes were not the only members of that important class. Whether the milieu of human culture really does have what it takes to get a form of Darwinism going, I am not sure. But in any case that question is subsidiary to my concern. Chapter 11 will have succeeded if the reader closes the book with the feeling that DNA molecules are not the only entities that might form the basis for Darwinian evolution. My purpose was to cut the gene down to size, rather than to sculpt a grand theory of human culture.

(3) ... *memes should be regarded as living structures, not just metaphorically but technically*

DNA is a self-replicating piece of hardware. Each piece has a particular structure, which is different from rival pieces of DNA. If memes in brains are analogous to genes they must be self-replicating brain structures, actual patterns of neurological wiring-up that reconstitute themselves in one brain after another. I had always felt uneasy spelling this out aloud, because we know far less about brains than about genes, and are therefore necessarily vague about what such a brain structure might actually be. So I was relieved to receive very recently a very interesting paper by Juan Delius of the University of Konstanz in Germany. Unlike me, Delius doesn't have to feel apologetic, because he is a distinguished brain scientist whereas I am not a brain scientist at all. I am delighted, therefore, that he is bold enough to ram home the point by actually publishing a detailed picture of what the neuronal hardware of a meme might look like. Among the other interesting things he does is to explore, far more searchingly than I had done, the analogy of memes with parasites; to be more precise, with the spectrum of which malignant parasites are one extreme, benign 'symbionts' the other extreme. I am particularly keen on this approach because of my own interest in 'extended phenotypic' effects of parasitic genes on host behavior (see Chapter 13 of this book and in particular chapter 12 of *The Extended Phenotype*). Delius,

by the way, emphasizes the clear separation between memes and their ('phenotypic') effects. And he reiterates the importance of coadapted meme-complexes, in which memes are selected for their mutual compatibility.

(4) '*Auld Lang Syne*'

'Auld Lang Syne' was, unwittingly, a revealingly fortunate example for me to have chosen. This is because, almost universally, it is rendered with an error, a mutation. The refrain is, essentially always nowadays, sung as 'For the sake of auld lang syne', whereas Burns actually wrote 'For auld lang syne'. A memically minded Darwinian immediately wonders what has been the 'survival value' of the interpolated phrase, 'the sake of'. Remember that we are not looking for ways in which *people* might have survived better through singing the song in altered form. We are looking for ways in which the alteration *itself* might have been good at surviving in the meme pool. Everybody learns the song in childhood, not through reading Burns but through hearing it sung on New Year's Eve. Once upon a time, presumably, everybody sang the correct words. 'For the sake of' must have arisen as a rare mutation. Our question is, why has the initially rare mutation spread so insidiously that it has become the norm in the meme pool?

I don't think the answer is far to seek. The sibilant 's' is notoriously obtrusive. Church choirs are drilled to pronounce 's' sounds as lightly as possible, otherwise the whole church echoes with hissing. A murmuring priest at the altar of a great cathedral can sometimes be heard, from the back of the nave, only as a sporadic sussuration of 's's. The other consonant in 'sake', 'k', is almost as penetrating. Imagine that nineteen people are correctly singing 'For auld lang syne', and one person, somewhere in the room, slips in the erroneous 'For the sake of auld lang syne'. A child, hearing the song for the first time, is eager to join in but uncertain of the words. Although almost everybody is singing 'For auld lang syne', the hiss of an 's' and the cut of a 'k' force their way into the child's ears, and when the refrain comes round again he too sings 'For the sake of auld lang syne'. The mutant meme has taken over another vehicle. If there are any other children there, or adults unconfident of the words, they will be more likely to switch to the mutant form next time the refrain comes round. It is not that they 'prefer' the mutant form. They genuinely don't know the words and are honestly eager to learn. Even if those who know better indignantly bellow 'For auld lang syne' at the top of their voice (as I do!), the correct words happen to have no conspicuous consonants, and the mutant form, even if quietly and diffidently sung, is far easier to hear.

A similar case is 'Rule Britannia'. The correct second line of the chorus is 'Britannia, rule the waves'. It is frequently, though not quite universally, sung as 'Britannia rules the waves'. Here the insistently hissing 's' of the meme is aided by an additional factor. The intended meaning of the poet (James Thomson) was presumably imperative (Britannia, go out and rule the waves!) or possibly subjunctive (let Britannia rule the waves). But it is superficially easier to misunderstand the sentence as indicative (Britannia, as a matter of fact, does rule the waves). This mutant meme, then, has two separate survival values over the original form that it replaced: it sounds more conspicuous and it is easier to understand.

The final test of a hypothesis should be experimental. It should be possible to inject the hissing meme, deliberately, into the meme pool at a very low frequency, and then watch it spread

because of its own survival value. What if just a few of us were to start singing 'God saves our gracious Queen'?

(5) *If the meme is a scientific idea, its spread will depend on how acceptable it is to the population of individual scientists; a rough measure of its survival value could be obtained by counting the number of times it is referred to in successive years in scientific journals.*

[Sorry, I left this note out. It's rather long, and contains 3 figures (relatively hard to copy and put into an HTML page) that unfortunately *are* important to the note's text -- and anyway, the note is probably of interest only to settled bureaucratic scientists concerned mainly with the # of times their own publications are quoted in papers by others. :-):-) But !, since you have read so far, I think you are pretty interested in this stuff -- please consider buying the book ! I think it really would be a worthwhile investment in yourself.]

(6) *The computers in which memes live are human brains.*

It was obviously predictable that manufactured electronic computers, too, would eventually play host to self-replicating patterns of information -- memes. Computers are increasingly tied together in intricate networks of shared information. Many of them are literally wired up together in electronic mail exchange. Others share information when their owners pass floppy disks around. It is a perfect milieu for self-replicating programs to flourish and spread. When I wrote the first edition of this book I was naïve enough to suppose that an undesirable computer meme would have to arise by a spontaneous error in the copying of a legitimate program. Alas, that was a time of innocence. Epidemics of 'viruses' and 'worms', deliberately released by malicious programmers, are now familiar hazards to computer-users all over the world. [Unoriginal paragraph break]

My own hard disc has to my knowledge been infected in two different virus epidemics during the past year, and that is a fairly typical experience among heavy computer users. I shall not mention the names of particular viruses for fear of giving any nasty little satisfaction to their nasty little perpetrators. I say 'nasty', because their behavior seems to me morally indistinguishable from that of a technician in a microbiology laboratory, who deliberately infects the drinking water and seeds epidemics in order to snigger at people getting ill. I say 'little', because these people are mentally little. There is nothing clever about designing a computer virus. Any half-way competent programmer could do it, and half-way competent programmers are two-a-penny in the modern world. I'm one myself. I shan't even bother to explain how computer viruses work. It's too obvious.

[Hear, hear ! So even Dawkins is not immune to burst off in 'flames' and in useless gratuitous morality and ethics. :-):-) Still, nevertheless, this note (bar the moralisms) does contain some interesting stuff.]

What is less easy is how to combat them. Unfortunately some very expert programmers have had to waste their valuable time writing virus-detector programs, immunization programs and so on (the analogy with medical vaccination, by the way, is astonishingly close, even down to the injection of a 'weakened strain' of the virus). The danger is that an arms race will develop, with

each advance in virus-prevention being matched by counter-advances in new virus programs. So far, most anti-virus programs are written by altruists and supplied free of charge as a service. But I foresee the growth of a whole new profession -- splitting into lucrative specialisms just like any other profession -- of 'software doctors' on call with black bags full of diagnostic and curative floppy disks. I use the name 'doctors', but real doctors are solving natural problems that are not deliberately engineered by human malice. My software doctors, on the other hand, will be, like lawyers, solving man-made problems that should never have existed in the first place. In so far as virus-makers have any discernible motive, they presumably feel vaguely anarchistic. I appeal to them: do you really want to pave the way for a new cat-profession? If not, stop playing at silly memes, and put your modest programming talents to better use.

(7) *Blind faith can justify anything.*

I have had the predictable spate of letters from faith's victims, protesting about my criticisms of it. Faith is such a successful brainwasher in its own favor, especially a brainwasher of children, that it is hard to break its hold. But what, after all, is faith? It is a state of mind that leads people to believe something -- it doesn't matter what -- in the total absence of supporting evidence. If there were good supporting evidence then faith would be superfluous, for the evidence would compel us to believe it anyway. It is this that makes the often-parroted claim that 'evolution is a matter of faith' so silly. People believe in evolution not because they arbitrarily want to believe it but because of overwhelming, publicly available evidence.

I said 'it doesn't matter what' the faithful believe, which suggests that people have faith in entirely daft, arbitrary things, like the electric monk in Douglas Adam's delightful *Dirk Gently's Holistic Detective Agency*. He was purpose-built to do your believing for you, and very successful at it. On the day that we meet him he unshakably believes, against all the evidence, that everything in the world is pink. I don't want to argue that things in which a particular individual has faith are necessarily daft. They may or may not be. The point is that there is no way of deciding whether they are, and no way of preferring one article of faith over another, because evidence is explicitly eschewed. Indeed the fact that true faith doesn't need evidence is held up as its greatest virtue; this was the point of my quoting the story of Doubting Thomas, the only really admirable member of the apostles.

Faith cannot move mountains (though generations of children are solemnly told the contrary and believe it). But it is capable of driving people to such dangerous folly that faith seems to me to qualify as a kind of mental illness. It leads people to believe in whatever it is so strongly that in extreme cases they are prepared to kill and die for it without the need for further justification. Keith Henson has coined the name 'memeoids' for 'victims that have been taken over by a meme to the extent that their own survival becomes inconsequential ... You see lots of these people on the evening news from such places as Belfast or Beirut'. Faith is powerful enough to immunize people against all appeals to pity, to forgiveness, to decent human feelings. It even immunizes them against fear, if they honestly believe that a martyr's death will send them straight to heaven. What a weapon! Religious faith deserves a chapter to itself in the annals of war technology, on an even footing with the longbow, the warhorse, the tank, and the hydrogen bomb.

(8) *We, alone on earth, can rebel against the tyranny of the selfish replicators.*

The optimistic tone of my conclusion has provoked skepticism among critics who feel that it is inconsistent with the rest of the book. In some cases the criticism comes from doctrinaire sociobiologists jealously protective of the importance of genetic influence. In other cases the criticism comes from a paradoxically opposite quarter, high priests of the left jealously protective of a favorite demonological icon! Rose, Kamin, and Lewontin in *Not in Our Games* have a private bogey called 'reductionism'; and all the best reductionists are also supposed to be 'determinists', preferably 'genetic determinists'.

Brains, for reductionists, are determinate biological objects whose properties produce the behaviors we observe and all the states of thought or intention we infer from that behavior ... Such a position is, or ought to be, completely in accord with the principles of sociobiology offered by Wilson and Dawkins. However, to adopt it would involve them in the dilemma of first arguing the innateness of much human behavior that, being liberal men, they clearly find unattractive (spite, indoctrination, etc.) and then to become entangled in liberal ethical concerns about responsibility for criminal acts, if these, like all other acts, are biologically determined. To avoid the problem, Wilson and Dawkins invoke a free will that enables us to go against the dictates of our genes if we so wish ... This is essentially a return to unabashed Cartesianism, a dualistic *deus ex machina*.

I *think* that Rose and his colleagues are accusing us of eating our cake and having it. Either we must be 'genetic determinists' or we believe in 'free will'; we cannot have it both ways. But -- and here I presume to speak for Professor Wilson as well as for myself -- it is only in the eyes of Rose and his colleagues that we are 'genetic determinists'. What they don't understand (apparently, though it is hard to credit) is that it is perfectly possible to hold that genes exert a statistical influence on human behavior while at the same time believing that this influence can be modified, overridden or reversed by other influences. Genes must exert a statistical influence on any behavior pattern that evolves by natural selection. Presumably Rose and his colleagues agree that human sexual desire has evolved by natural selection, in the same sense that anything ever evolves by natural selection. They therefore must agree that there have been genes influencing their sexual desires -- in the same sense as genes ever influence anything. Yet they presumably have no trouble with curbing their sexual desires when it is socially necessary to do so. What is dualist about that? Obviously nothing. And no more is it dualist for me to advocate rebelling 'against the tyranny of the selfish replicators'. We, that is our brains, are separate and independent enough from our genes to rebel against them. As already noted, we do so in a small way every time we use contraception. There is no reason why we should not rebel in a large way, too.

Abstract

Certain arguments generated by political and administrative actors find their way to tangible policy actions, others do not. Some information is embraced by actors in institutional systems, whereas other arguments and facts can be ignored with impunity. Apparently, institutional structures constitute a persistent tendency to favour particular arguments at the cost of others. In decision making processes, i.e. processes during which a selection is to be made among various alternative policy options, institutional structures, consisting of existing decision rules and practices, operate as an information filter creating a conceptual bias.

This article spots the issue of political decision making from an evolutionary and memetics perspective, employing terms such as variation and selection, mutation and replication, information transmission and fit concepts. With the aid of the evolutionary theoretical framework, the mechanism that decides why and when certain concepts are deemed fruitful and others die is pinpointed. Examples from the field of investments in transport infrastructure in England are used to clarify the line of thought. At the end, the evolutionary perspective derived from biology is compared to well-known authors in political science to see if complementary ground can be found.

1 Introduction

Certain arguments generated by political and administrative actors find their way to tangible policy actions, others do not. Some information is embraced by actors in institutional systems, whereas other arguments and facts can be ignored with impunity. Apparently, existing decision rules and practices constitute a persistent tendency to favor particular arguments at the cost of others. Schattschneider (1965), a well-known political scientist, dubbed the implicit or explicit favoring of certain actors and subjects and the waiving of others mobilization of bias; a bias built into the institutional structure addressing the finite attention of powerful actors to certain policy-matters at the expense of others.

This article introduces an additional element to mobilization of bias: concepts. Decisions are often made with the help of conceptual models indicating which information is relevant and to be searched and which is not to be paid any attention to. The political agenda not only favors specific actors and policy-issues, but also the way they are addressed. Argumentative practices

follow the bias built into these conceptual decision models and thereby determine the criteria on which policy-decisions are based. The models frame both importance and interpretation of concepts, conceptions, reasonings and data. Some arguments are generated because the institutional structure evokes them; others never even see the light of day. Some arguments are selected in and transformed into actual decisions; others are weeded out before even reaching the finishing post. Argumentative practices that have been institutionalized are part of the 'dominant institutional complex' and guide the way to the gathering of decisionally relevant information. Reasonings and data along this line are successful because they fit into the conceptual frame embraced by actors possessing the prevalent policy instruments (funds, properties, legal competences). Arguments which are either not produced, which remain latent or which are discussed but ignored when it comes to decision-making do not comply with the criteria defined by those 'in power' in the institutional system. They are relegated to the 'recessive complex', a discourse remaining mainly under the surface. Apparently, we are dealing with a selective mechanism for concepts here: the present institutional structure consists of existing political rules and argumentative practices that act as an information filter for incoming arguments and data.

In this article, the mobilization process described above is reframed in evolutionary terminology. I claim that current theories using an institutional framework can be enriched by observing them as processes in which a certain variation of concepts is created and further on selected by the institutional structure, which acts as a selective environment, as a filter concepts have to pass before having any material consequences. If we consider individual concepts as single memes (Price & Shaw 1996), conceptual frameworks as memplexes and information filters consisting of selection criteria as memetic filters as described by Dennett (1995), we may bring political science and memetics, the conceptual version of biological evolutionary theory, much closer to each other. Observing institutional development, exchange of argumentation and actor behavior as processes of evolutionary change adds an element of dynamics to political analysis that in my view is often overlooked. Evolutionary theory is by its nature engaged in describing and explaining mechanisms of mutation, change and development and is therefore a bride bringing in a very attractive dowry: a fruitful analogy. [Note 1]

Memetics, on the other hand, being a theoretically rich and promising framework badly needs empirical filling. This article aims to provide this type of evidence by linking memetics to conceptual change in political decision making.

In section 2, 'Institutional structures as information filters', I will first present the idea of information filters as it was coined by Dennett (1995). In a situation of information abundance, a framework of rules evolves to base selections on. This very same mechanism works in both the selection of good poetry and the choice between policy alternatives, as will be shown with an example derived from English transport policy.

As information filters have the form of institutional structures when policy-making is concerned, we will then dive into the definition and description of institutions. Section 3, 'Institutional structures, behavioral bias and conceptual bias', will highlight the distinction between behavioral and conceptual institutions and their interplay in the institutional structure as a whole. This look at institutional structures synthesizes current insights. From the literature we know that formal and informal power structures can exclude certain actors from the policy-process. We also know

that the use of a dominant terminology may prevent certain ideas or certain notions from being aired.

Section 3 combines these two interdependent aspects and shows how their interplay influences the gathering and selection of information and alternatives.

Section 4, 'Evolution of conceptual bias in institutional structures', gives some examples of institutional change. Particular concepts which first were sieved out by the filter later on came to be embraced by powerful actors and incorporated in the newly adapted institutional complex. This can happen because initially recessive concepts sometimes keep lingering around and 'wait' for some later opportunity. Dominant actors usually have self-interested motives for such a sudden volte face.

'Institutional selection and fit concepts', the fifth section, recapitulates the evolutionary insights in this article and tries to identify the essentials of a 'fit concept', a concept that finds its way through the filter and is thus selected in. What mechanisms decide whether a concept becomes dominant in an institutional structure?

The concluding section 6 investigates how the approach propagated here relates to other political theories about learning as developed by Sabatier (1987) , Sabatier & Jenkins-Smith (1993), Hajer (1995) and Hall (1993).

2 Institutional structures as information filters

In modern evolutionary biology organisms' genes or geneplexes are considered the unities which are replicated from generation to generation. Organisms are built up following the construction plan contained in their genes and after procreation copy this genetic material to their offspring. They are therefore the carriers of genetic information. Their role is not restricted to that of being only passive vehicles however. Among different organisms or populations of organisms survival and procreation rates differ. They live in a natural environment that allows certain exemplars to survive and prosper, while others fade away or starve. This natural environment leads some (populations of) organisms to survive and spread where others do not. It is a selection mechanism in the sense that only the genetic material of the successful is replicated unto following generations. The differential genetic replication rates between successful and unsuccessful lineages of carriers result in genetic evolution across generations.

Recently, this line of evolutionary thought has been enlarged to the social world as well. Just as we can observe a replication process of genetic information in the world of biology, there is a replication process of memetic information in the world of thought and learning. Ideas ('memes') living in the one actor's brain can by means of communication be replicated to other brains, and the more this occurs to a certain idea the higher is its replication rate and the greater is its success. A very intriguing thought. But if, according to this analogy, memetic information replaces genetic information and if we see an actor's brains as the carriers, what can we say about the natural selection environment? What ruthless selective filter sieves out the unsuccessful ideas? Dennett (1993) gives an impression of what a memetic filter looks like. Here is an

extensive quote telling how 'good poems' in an electronic network may be traced in a vast pool of poetic dump produced by both brilliant and mediocre poets.

John McCarthy, one of the founders of Artificial Intelligence (...) once suggested to a humanist audience that electronic-mail networks could revolutionize the ecology of the poet. Only a handful of poets can make their living by selling poems, McCarthy noted, because poetry books are slender, expensive volumes purchased by very few individuals and libraries. But imagine what would happen if poets could put their poems on an international network, where anybody could read them or copy them for a penny, electronically transferred to the poet's royalty account. This could provide a steady source of income for many poets, he surmised. Quite independently of any aesthetic objections poets and poetry-lovers might have to poems embodied in electronic media, the obvious counter hypothesis arises from population memetics. If such a network were established, no poetry-lover would be willing to wade through thousands of electronic files filled with doggerel, looking for the good poems; there would be a niche created for various memes for poetry filters. One could subscribe, for a few pennies, to an editorial service that scanned the infosphere for good poems. Different services, with different critical standards, would flourish, as would services that screened, collected, formatted and presented the works of the best poets in slender electronic volumes which only a few would purchase. In other words, the memes for editing and criticism will find niches in any environment in the infosphere; they flourish because of the short supply and limited capacity of minds, whatever the transmission media between minds. Do you doubt this prediction? If so, I'd like to discuss framing a suitable wager with you. Here once again, as we have seen so often in evolutionary thinking, explanation proceeds by an assumption that the processes -whatever their media, and whatever the contingent zigs and zags of their particular trajectories- will home in on the forced moves and other Good Tricks in the relevant space.

The structure of filters is complex and quick to respond to new challenges, but of course it doesn't always 'work'. The competition among memes to break through the filters leads to an 'arms race' of ploy and counterploy, with ever more elaborate 'advertising' raised against ever more layers of selective filters (Dennett 1993: 350).

The quality selection devices Dennett speaks of consist of a framework of search rules or heuristics. Poems meeting certain standards in terms of poet's name and reputation, employed vocabulary, length, subject, rhyme or melody and conformity to style characteristics will flow through, while lousy amateur near-sonnets or unconventional absurdist products by unknown artists won't find their way out of the electronic maze. In the end, the brain of the actor using the search device will only copy the ideas contained in the selected poems: the filter did its work.

Now suppose civil servants working at the English Department of Transport have to decide on the future of the national transport network. They are responsible for the funding of projects, programs or bids other actors submit to them. They do not have the financial means to approve of them all, so they have to make a warranted selection among them. This leaves them no other choice but to establish criteria by which they can determine what information is relevant. If they need to justify the quality of their selection they cannot escape developing rules telling which projects can be considered valuable and which cannot.

To cope with information overload the Department of Transport (**DoT**) in London has developed a cost-benefit analysis (**COBA**) to evaluate proposals submitted by local governments. As local governments can hardly levy any financial means by themselves, they rely on central funds for the realization of infrastructure projects. Well aware of this situation, DoT conscientiously applies this COBA model and has promulgated a paper explaining the functioning of the priority-setting method enumerating criteria by which the desirability of infrastructure projects can be determined. It pays specific attention to the following aspects (DoT 1989, May 1991, DoT 1994, Steer 1995, De Jong 1999):

- financial profitability
- at least 50% financial contributions from the private sector and as many private participants as possible
- improvement of run down inner city areas
- the increase or decrease in externalities caused by the project

Just like the poetry filters select poetic products that meet certain standards, COBA's criteria weed out project bids with low scores on the abovementioned criteria. Local governments' financial claims should be substantiated by a summing up of information on all of these aspects and preferably expressing the total value of projects in the monetary unit: profitability in hard pounds. There clearly is a bias in COBA. It explicitly excludes user benefits from consideration, claiming that they will be discounted in the market price. On the other hand, the rise in market value in certain areas generated by new infrastructure should be included in the calculation. These arguments set public transport at a significant disadvantage (May 1991). Benefits and costs are only calculated for criteria summed up in the method of appraisal and their outcoming ratios reflect the conceptual bias.

To put it differently, DoT desires rather detailed information from local governments before they can get the money they need. To make them understand what kind of data they should deliver, it proposes an informational format stipulating the aspects they should pay attention to and how they are expected to add them all up. Using the format is not compulsory; if they wish to calculate profitability in their own way, they are free to do so. But when they submit their proposal in London, at least they are abreast of the criteria they will be judged on. Dennett's poets are in exactly the same position, they are still allowed to put experimental or amateur work on the web, but their chances for selection are minimized by the format of the filter. They may still avoid treating love and sex as the primary issues in their work, but they risk missing out lots of readers.

Rigorous and uncompromising application places dissident local authorities in a difficult position. Information they possibly attach value to will not make it through the COBA filter. As a result, their pet projects will not receive the required funding.

How do local governments generally react in a competitive environment where their local brothers are not friends but foes? They adapt to London standards or die. Authorities that have their bids sanctioned underscore the profitability of their projects, introduce an impressive list of well-known and less well-known banks, project developers and consultancy firms whose actual contribution is sometimes doubtful, ask for new roads and by-passes around the city-centre and

invest only in 'shinier kinds' of public transport such as tramways leading to the central areas. Furthermore, as DoT mentions in its 'S56-circular', it is highly irrational to extensively calculate environmental benefits which are not or not easily quantifiable. On the other hand, it is highly rational to have good contacts with the Government Offices, deconcentrated national offices in the regions. They know all the ins and outs of London decision-making and can give good advice on how and when to plug bids in and what terminology is appreciated in the capital. It is precisely this compliance which begets both success for the money-claimants and materialization of the COBA-worldview for the money-provider, a perhaps even bigger success. As one can easily understand, the effect a poetry filter has on individual poets, at least those desiring to be read, will be no different. They too will cunningly market their products and start treating each other as rivals in the infospace. [note 2]

To conclude, the complex of rules indicating what criteria or standards poems or transport investment bids should meet to be in the selection and what actor(s) have a say on this matter in policy-making is called 'institutional structure'.

3 Institutional structures, behavioral bias and conceptual bias

An enormous number of volumes from different authors and various scientific disciplines have appeared on 'institutions', but little common ground has been found. Here, we follow Simon (1982, 1992), North (1981, 1990), March and Olsen (1976, 1989) and Hall (1993).

Institutions are rules which enable actors to cope with uncertainty when making decisions. [Note 3]

One can say that all complex choices actors need to make require an amount of information not directly available. It is not always feasible to collect this information; it is either too expensive, too time-consuming or too annoying. Nor is it always necessary; knowledge gathered in the past has often been recorded in terms of usual practices, norms of conduct, traditions or standard operating procedures. The decision rules implied in these institutions, 'correct' or not, are readily available and may save actors hugely in terms of transactions costs. If an actor has a decision model based on experience, it does not make sense to put it in doubt every time it is used: rules are very often functional and reassuring. We can clearly see the parallel with the filter mentioned in preceding section.

For the purpose of this article, showing how mobilization of conceptual bias works, the above mentioned definition of institutions is still too general. I would therefore like to make a double distinction resulting in a two by two matrix of types of institutions.

Institutions can be either formal or informal. Formal institutions are legal-verbal procedures reflecting the official 'rules of the game'. Informal institutions are the non-verbal, non-official current practices developed by players during the game.

Institutions can be either conceptual or behavioral. Conceptual institutions are rules indicating how actors should think about an impending choice; they delimit the interpretative freedom.

Behavioral institutions are rules that decide how actors should or should not act; they restrict the interactive freedom. [Note 4]

3.1 Four types of institutions

<i>Type of institution</i>	<i>Formal</i>	<i>Informal</i>
<i>Behavioral; rules for appropriate interaction</i>	Procedures, arrangements	Behavioral codes, Norms of conduct
<i>Conceptual; rules for appropriate interpretation</i>	Decision rules, standards, criteria	Approaches, visions, conceptions, frames

The ensemble of these various rules in a specific (policy) area is called the institutional complex or institutional structure. Arguments brought in by different actors are 'filtered' by this complex, and only those fitting in with the dominant complex embraced by the currently most powerful actors acquire influence on the 'real' decision making. It seems that concepts are 'fit' when they 'fit in'. Though this is true to large extent, it is also highly tautological. If concepts did not survive, they apparently didn't fit in. Fortunately, this is not totally true. Some concepts do not conform to the institutional standards at first, but do reach institutional hegemony after fierce conceptual struggle. Other concepts should be fit considering their possession of the properties demanded by the institutional environment, and yet don't make it if competition is too strong. [Note 5]

One important point still begs clarification. I have mentioned that institutional structures have a bias in favor of certain arguments and facts at the expense of others. I have also written that institutional complexes function as a selective environment for concepts introduced by actors. Does this mean that 'structures' are the same as 'complexes' and that 'arguments and facts' equal 'concepts'?

The answer to the first question is yes, more or less. The only slight difference is that the word 'complex' sounds more evolutionary and more open to the conceptual side of choice-making than 'structure', which has a static ring to it. Nevertheless, the terms are interchangeable here.

The answer to the second question is less straightforward. So far I have used the terms concepts, conceptions, arguments, facts and criteria rather loosely, as is unfortunately quite often also the case in how the term 'meme' is generally used. This conceptual informality will end from now on. Concepts are singular words having a particular significance. They can be seen as the smallest thinkable entity which can be replicated. Conceptions or conceptual systems are a totality, a combination of concepts forming a meaningful frame. Arguments are assumed causal connections between concepts, which provide insight into a specific question or problem. Giving an argument actually means picking out two or a few concepts from a conceptual system which have a relation with each other to address a particular issue. If a specific argument is widely accepted as being the correct way to address a specific issue at all times, it becomes a criterion: the argument is formalized. Last but not least, facts are events or data that are shown to prove

particular arguments right or wrong. They can be either qualitative or quantitative, but are only meaningful in the context of the argument for which they are used.

Toulmin (1972) wrote a wise phrase saying that concepts are micro-institutions, and institutions are macro-concepts. Disregarding the fact that institutional complexes not only consist of conceptual elements, but of behavioral elements as well, it helps to understand how institutional complexes composed of conceptual notions generally select like-minded and related concepts and occasionally incorporate new concepts within this system, which then become micro-institutions. As a result, institutional change occurs. Which micro-institutions will be part of the macro-complex and when they will obtain their place depends mainly on the relations contained in the behavioral institutions. Dominant actors have their interests and are supportive of concepts that promote these interests.

4 Evolution of conceptual bias in institutional structures

The preceding sections have demonstrated that institutional structures work as filters that select certain incoming concepts in and weed others out. But the relationship between concepts and institutions can also be approached from a more dynamic angle: how previously ignored concepts become institutionalized themselves, succeeding thereby in changing argumentative links in the till then dominant institutional complex. This does not happen all that often, however; it requires political momentum. Big changes only come to be when the rigid existing complex can no longer deal with societal problems, such as abnormal congestion or exuberant pollution (Krasner 1984, 1988). Such situations put the dominant complex under strain and can lead to institutional evolution via two different paths which I will describe underneath:

4.1 The complete replacement of the conceptual framework by another (paradigm shift)

In this case, the dominant actor(s) is/are confronted with increased resistance from recessive actors that no longer accept its/their conceptual and behavioral hegemony and challenge the existing the institutional structure as a whole. Following the increased behavioral strength of the recessive actors, a fierce conceptual struggle begins in which the dominant actor(s) also loses the conceptual initiative and finally has to give way.

In the South East of England counties and districts were confronted with DoT's fairly centralist attitude to infrastructure planning, as described in the section 2. Feeling frustrated and noting they were continually by-passed and competed by each other while London actively exploited their weak positions, they decided to get in touch with one another more intensely. Some local governments realized they had good roads and mediocre public transport and for others the situation was the other way around. Acknowledging their interdependence and regrouping together they were able to restructure the negotiations with London along regional lines (DoE/SERO 1994, SERPLAN 1994, Steer 1995). Consequently, the behavioral institutions started to change. After an 'initiation process' in which they had to get used to cooperating with their former rivals, they established 'package bids' with proposals for funds aimed at the whole region. They challenged London's hegemony by speaking with one voice. Besides they found active conceptual support from the London and South East Regional Planning Conference, a successful advisory organization funded by all local governments in the region that catalyzed and

facilitated mutual adaptation. It had developed knowledge in spatial planning and environmental costs and has usually been ahead in conceptual innovation. As DoT sensed that vital information was no longer spontaneously provided from local authorities to itself, but only to other regional authorities, it accepted the London and South East Regional Planning Conference as a regular institutional body. In this way the package bid approach replaced the application of COBA.

The coherence of thought implied by a package of measures does not lend itself well to a scheme-by-scheme appraisal, which is the established basis on which funding decisions are made. Funding agencies will no doubt continue to ask for a cost-benefit assessment of individual projects, but these appraisals do not answer the question inevitably posed by the package approach: what contribution to the overall strategy does this particular scheme or policy make? The aims of the overall strategy are not capable of expression in terms of quantified benefit-cost ratio targets. It follows that at the scheme, as well as strategy, level attempts will have to be made to develop new appraisal systems (Steer 1995: 204).

The basis for this investment approach was the 'Integrated Transport Studies' in which traffic trends from the past were not simply extrapolated to the future, but various effects of traffic growth were correlated with dynamic patterns of spatial evolution. In this approach the environmental and spatial effect in the region came much more to the fore, as well as a more holistic view of traffic streams. The change in the behavioral institutions, the stronger position of regional governments and their private representative, led to the institutionalization of a wholly new conceptual framework. As a consequence the old institutional complex was replaced by a new approach. DoT did try and continue to judge the package bids with the help of COBA (in effect the two 'filters' temporarily co-existed), but it gradually had to give way. In the end, the project bids for the South East were submitted to a completely changed filter.

4.2 A partial change in the conceptual framework (slight mutation)

In this less revolutionary case, dominant actors anticipate the weakening of their behavioral position and prevent it by allowing recessive actors to have some more influence by accepting a few of their recessive concepts. They integrate them into the dominant institutional structure to placate the recessive actors without having to give up the dominant paradigm. In this case, dominant actors are more forward-looking and do not have to go through the painful process of giving up funds, political positions or legal competences. They only have to consent to some conceptual adaptations in the institutional complex to accommodate and placate dissident actors.

DoT in London has for some decades applied a variant of COBA for the assessment of trunk roads and motorways. Until recently, the model utilized a purely demand based philosophy: if road congestion exceeded a certain threshold, more asphalt had to be constructed. The Transport Research Laboratory, a research organization outside the centre of the decision making network, had been criticizing the demand based line of thought since the beginning of the 1980s. They promoted the idea of so-called 'induced traffic': a higher supply of good infrastructure creates its own increased demand for transport. For this reason, when DoT had more roads built, automatically new and till then latent car drivers would suddenly appear on the road network. The conventional COBA model did not take such phenomena into account and therefore arranged for the accommodation of traffic it continually generated itself. Even though many

observers outside the Transport Research Laboratory were aware of this phenomenon, at that time the automobile lobby was too strong to push through any new concepts. The Special Advisory Commission on Trunk Roads Assessment (SACTRA), a high status advisory board for counseling on new motorway projects agreed, but felt the time was not yet right for a fundamental change in orientation. DoT also had many investment programs running, based on the existing model.

But by the mid nineties, popular support for the construction of more roads had declined tremendously. Environmental groups antagonized more strongly than ever against new inroads on British scenery. The conservative government decided to drastically curtail the budget for infrastructure planning and the accompanying taxes in order to increase its chances to win the elections. DoT was forced to adapt its ways and SACTRA issued an innovative report telling the nation that every new supply of infrastructure did indeed generate its own demand. DoT now voluntarily accepted the ideas in this official advice and redesigned COBA in line with the new more sober philosophy and had all running road projects recalculated and reweighed by SACTRA. Forty-nine formerly approved investments could be scrapped and cancelled. In this second case, the dominant actor was able to prevent a dramatic change in the institutional structure by allowing some conceptual mutation, but clearly within the existing conceptual framework (DoT 1994, CBI 1995).

5 Institutional selection and fit concepts

Considering the exchange of arguments as concepts waging a struggle for survival in institutional complexes gives us some valuable insights in the dynamics of decision making. But there is a philosophical problem here. Do concepts, mere words that is, actually struggle? Aren't concepts only puppets on strings, used as manipulative tools by humans or actors to serve their interests? They do not have a will of their own, do they?

In biology, there is an equivalent discussion concerning the 'levels of selection' (Brandon 1988). Leading theorists in evolutionary theory do not agree among themselves about these levels of selection. Some say that selfish genes really fight for their own subsistence and that they are the ones that live through generations. In that case individual organisms are no more than helpless vehicles that replicate invisible information codes vital to evolution (Dawkins 1976). In the social science analogy, this would imply that actors are only the means through which concepts are transferred and that real selection is 'executed' only on concepts. Others claim that organisms are the ones that matter when it comes to the weeding out process, not genes. As a result, the transplantation of genetical material depends on the survival and reproduction of their carriers. Organisms are not simple vehicles, but acting and interacting entities that during their lives 'determine' whether the genes according to which codes they are built deserve a future (Sober 1984).

For the process of conceptual evolution, this would mean that the success of actor fitness and behavior make a difference. They are active carriers of ideas, not passive vehicles, so in the end the survival of ideas depends on them. The last group of theorists focuses on whole populations of organisms. Considering a much larger time span and the success of species, subspecies or geographically dispersed groups within a species, these theorists generally conclude that

populations that are bigger or have a greater variation in their total 'geneplex' are also fitter in the long run. Besides, individual organisms may have a strong physical constitution but may lack the advantages of a protective social group (Brandon 1988). [Note 6]

As all lines of thought have a point, the decision on what the level of selection is cannot be definitively answered. Hull (1988) found a way out of this dilemma by introducing the difference between interactors and replicators. He defines them as follows:

- *Replicator: an entity that passes on its structure largely intact in successive replications.*
- *Interactor: an entity that interacts as a cohesive whole with its environment in such a way that this interaction causes replication to be differential.*

With the aid of these terms selection can be characterized succinctly as follows:

Selection: a process in which the differential extinction and proliferation of interactors cause the differential perpetuation of the relevant replicators.

Replicators and interactors are the entities that function in selection processes. Some general term is also needed for the entities that result from successive replications (Hull 1988: 408-409).

Now jumping back to the world of concepts and actors, we can see that actors interact with their environment causing concepts and conceptual systems to be replicated differentially. Concepts only tied to 'unfit', i.e. politically weak, actors are also unfit and have a greater chance of being weeded out. For concepts used by fit actors the opposite goes: they are often selected in. The differential success of actors to spread their concepts produces an outcome known as conceptual evolution.

At the outset of this article, we saw that concepts went through an institutional structure or 'filter' before being selected or not. According to Hull's definition, (inter)actors operate in an environment that causes (conceptual) replication to be differential. In the case of biological evolution it is the natural environment or ecology that causes the replication of genetic information to be differential. When speaking of conceptual evolution, it is the institutional structure that makes the procreation of some concepts more successful than the spreading of others.

If, following Toulmin (1972), we make a distinction between the creation of a variation of concepts (A) and their selection process (B), we acquire a full picture of the mechanisms behind conceptual evolution.

5.1 The creation of a variation of concepts

In the first place, actors must produce and utilize concepts before they are taken to their selective arena or filter. Concepts spread through replication from one actor to another. When concepts are replicated, small mutations or recombinations take place once in a while: their meaning changes, they acquire an extra connotation or they are applied to a different domain than previously. In other cases, whole new words are coined or invented. Conceptual mutation creates a greater variation of ideas to arise. In itself the replication of a concept from one actor to another only

generates conceptual change in the 'brain' of the receiving actor. But it may also provoke changes in this actor's perceptions and preferences and lead to different judgments of policies. This latter phenomenon leads them to act differently, carrying the germ of behavioral change.

5.2 The selection of concepts

The institutional complex reflects the dominant behavioral and conceptual practices developed from the past unto now and serves as a filter to the new incoming variation of concepts brought forward by actors. The behavioral institutions structure who is/are allowed to come in and perform what function with what means, the conceptual institutions are a conceptual system structuring what concepts and arguments are deemed meaningful by dominant actors. It contains the criteria applied to the selection of newly introduced concepts at a particular moment, but this too may evolve. If a specific concept has been replicated sufficiently to affect the wishes of dominant actors within the selective arena, it may institutionalize and become part of this filter. [Note 7]

If the existence of institutional structures can be established fairly easily by describing a system's written and oral rules of decision making, circumscribing what makes for the fitness of a concept is less self-evident. In the preceding sections, we saw that concepts in conformity with the criteria in the dominant complex are rather more successful than dissident ideas. Therefore, if dominant actors have developed and endorsed criteria for investment proposals demanding strong private participation and approve of schemes to promote renewal of run down inner city areas, investment proposals framed in those terms clearly have a higher probability to be selected than otherwise. But fitness is a stochastic and plural quality. It is stochastic in the sense that potentially viable concepts can fail for other reasons. They may enter the selection arena when other even stronger concepts happen to arrive as well or the actor presenting them may be out of grace. Fitness is plural or multiple in the sense that it has many sides to it. It is related to conceptual criteria as the ones just mentioned, but it is also related to behavioral criteria such as consulting friendly representatives from dominant actors for some good advice or allying with friend actors to reinforce one's position. However, generally it is the concepts' usefulness in the eyes of actors that makes them viable. Hull (1988) spoke of conceptual inclusive fitness: concepts are mainly replicated because of their ability to make individual actors understand and solve problems. In that sense they should be (1) applicable to a wide range of phenomena and (2) provide deep insight in these problems.

Also, when concepts have a structuring effect on other concepts, they will obtain a vital role in the web of a conceptual system or paradigm and attract or catch many other concepts in their webs. Concepts like 'the market', 'flexibility' or 'paradigm' seem to have these characteristics. If a sufficiently large number of actors share the opinion that a concept is needed or useful, one can say that it is 'fit'. This situation occurs in the two types of situations mentioned in the preceding section: namely (1) when a concept has already been institutionalized, or (2) when the current institutional structure is threatened or in crisis and actors recognize that the till then recessively lingering concept fills the problem-solving gap all concepts in the old complex were unable to fill.

As we saw in section 2, in some cases dependent actors have to adapt to the concepts imposed by more dominant ones. And in other cases, the ones in section 4, a whole group of not too strong actors may once in a while succeed in forcing dominant ones to retreat and by and by push in a wholly new conceptual system, realizing a 'paradigm shift' so to say. Often the combination of many fitness aspects together augments probability of survival, but some kind of 'chance' may always get in the way.

But increasing probabilities to be successful is not the same as predicting with certainty.

The evolutionary perspective may be helpful in understanding the way conceptual bias is mobilized, but framing decision making in terms of conceptual fitness does not help us to automatically forecast the success of investment proposals, even though we know they are verbally framed. That would have been too beautiful anyway. In the concluding section, the evolutionary framework presented in this article will be compared to the lines of thought by leading political theorists to see if some common or complementary ground can be found.

6 Conceptual learning in political theory

Even though 'conceptual evolution' is as far as I know a new term in the field of political science, this does not mean that attention to processes of policy learning has been absent. On the contrary, theorists such as Hall (1993), Sabatier (1988, 1993) and Hajer (1995) have tried to describe social or political learning in terms of 'social learning' and 'paradigm shifts' (Hall), 'advocacy coalitions' and 'belief systems' (Sabatier) and 'discourse coalitions' and 'story lines' (Hajer). After a short description of their central ideas, I will point out their similarities and differences with the line of thought in this article. [note 8]

6.1 Hall's work: Social learning and its three orders

Hall describes the process of policy learning as the acquisition of new information on the working of current policy measures and goals and the resulting changes in these measures and goals due to this new experience. He then disaggregates learning into three different types or 'orders':

First order learning concerns only adaptations in precise settings by which policy instruments and techniques are put to use.

Second order learning involves the types of policy instruments which are employed in the policy field and how possible combinations of these instruments are made.

Third order learning leads to a complete change in the overarching hierarchy of goals that guide policy in a particular field, in effect being a 'Gestalt change' or 'paradigm shift'.

Hall has rather specified ideas about this Gestalt or paradigm guiding public policymaking, and they bear a strong resemblance to the framework in this article:

(...) policies are made within some system of ideas and standards which is comprehensible and plausible to the actors involved. More precisely, policy makers customarily work within a framework of ideas and standards that specifies not only the goals of policy and the kind of instruments that can be used to attain them, but also the very nature of the problems they are meant to be addressing. Like a Gestalt, this framework is embedded in the very terminology through which policymakers communicate about their work, and it is influential precisely because so much of it is taken for granted and not amenable to scrutiny as a whole. I am going to call this interpretive framework a policy paradigm (Hall 1993: 279).

Hall pays attention to different levels of learning, his terminology is slightly different and in this article the emphasis on the process of conceptual evolution is more important, but there clearly seems to be some common ground.

6.2 Sabatier's work: advocacy coalitions holding incompatible belief systems

Sabatier claims that at the heart of certain policy debates, between groups of actors there is not just a clash of ad hoc arguments, but an incompatibility of deeper lying belief systems consisting of diverging images of man, society and administration. He explicitly bases his term 'belief systems' on Kuhn's scientific 'paradigms'. The prime example of a belief system struggle for which it is impossible to find definitive compromises, is the debate between economy and ecology. The materialist, efficiency assumptions on which the one, and the post-materialist sustainability assumptions on which the second, thrives cannot be unisoned at an abstract level. For this reason, both will basically remain distinct belief systems that conflicting groups of actors align around.

Incompatibility in the abstract, however, does not imply that at the level of more specific policy measures, concessions from both sides are impossible. The only manner to make decisions robust enough to be effective is either to push through one of both approaches by forming a coalition of actors strong enough to take control of all necessary policy instruments or to build compromises between both coalitions. The gap between a belief system and concrete measures can be bridged by translating the central assumptions to more peripheral elaborations. In this way, choices that boost the economy may be prevented from harming the environment or decisions can be made that reduce pernicious emissions while at the same time benefiting production processes. Pollution prevention may pay, as ecological modernism has it. By incorporating peripheral ideas from the enemy belief system in their own framework, an advocacy coalition can learn.

To conclude, agreement in the abstract about belief systems will for ever remain impossible, but ephemeral junctions between them are not. As a result, the latter aspect keeps the policy process going and learning, while the first keeps on producing struggles.

6.3 Hajer's work: discourse coalitions producing potentially compatible story lines

Hajer finds much of value in Sabatier's approach, but he emphatically rejects the idea that any core belief systems exist. Following a more post-modernist line, he explains how policies consist of narratives composed of competing story lines. Different actors employ different narratives and

once they have come to a textual agreement, one may say that a new, possibly innovative discourse has institutionalized. As there are no core assumptions coalitions of actors can be pinned down on, there might very well be diverging discourses, but they are not by necessity incompatible. Newly created and creative story lines introduced to the ongoing debate can displace old ones if they have a high potential of being picked up by others. However, as in Sabatier's case, some actors are more equal than others. When this line of reasoning is translated to discourses, it appears that some discourse coalitions are more potent than others. Hajer defines discourse coalitions as 'assemblages of ideas, concepts and categories through which meaning is given to phenomena'. Those 'in power' having their say on what should financially or physically happen determine largely which discourses overpower others and in what manner.

To conclude, as story lines instead of core assumptions decide on the orientation of political debates there is no essential incompatibility between different approaches; they are not immobile, but evolve. No essence can be established in any narrative. Still, some discourses win, while others lose, depending on institutional structures. By inventing new attractive story lines, losers might recover their lost ground.

6.4 Similarities, differences and surplus value

Apart from certain evident conflicting points between the various approaches to policy learning, there are two remarkable points of agreement.

Firstly, they all implicitly or explicitly refer to lines of thought developed in the philosophy of science, mainly Kuhn's paradigms (1962). Hajer and this author are more hesitant in following the paradigm approach, as the incompatibility of (policy) paradigms is not self-evident or probably even wrong. Words or concepts may have no essential meaning, but adapt their significance when being referred to other words or concepts, as Toulmin (1972) and Hull (1988) have clearly shown. But still, the theories of political learning all originate to an important extent in the philosophy of science.

Secondly, all authors consider both aspects of political power and the exchange of ideas as crucial to policy learning. In fact, it is precisely their intertwinement which lies at its basis. Or, as Hall beautifully summarizes:

The important point here is that 'powering' and 'puzzling' often go together. Both are dimensions of the process whereby policy changes, especially in democratic polities, whose institutions tend to combine the two endeavors. Politicians compete for office precisely by propounding new solutions to collective problems which appeal to the electorate. Officials advance their own fortunes within the bureaucracy partly by devising new approaches to old dilemmas. The institutional arrangements designed to marry the public interest to private interests in a democracy rarely work perfectly, but they do operate so as to militate against a rigid distinction between power-based and ideas-based models of politics. The competition for power can itself be a vehicle of social learning (Hall 1993: 289).

Nevertheless, the approach in this article has been different from or complementary to the others in two respects. It has highlighted the role of the existing institutional structure at a particular

moment in time in filtering the incoming new information. It has also focused on the survival chances of new information by taking notice of 'fitness aspects'. Both elements shed some light on the mechanisms behind conceptual evolution and may provide additional insights as compared to those already existing. On the other hand, a theory looking mainly at concepts and much less on policy instruments and techniques may be too strongly verbally oriented. In that sense, Hall's framework can add to the insights developed here.

Acknowledgements

This paper was written after intense and intensive discussion with my colleague and friend Hans Cees Speel. I mainly owe him for his explanations of the working of 'selective environments' in biology and the 'science of memetics'. Frans van Waarden, Joop Koppenjan and Bert Enserink also gave valuable comments.

Notes

Even though most of the current evolutionary terminology can be traced back to great masters in biology, it finds increasing application in the social sciences. Philosophical biologists or philosophers of biology such as Toulmin (1972), Dawkins (1976), Sober (1984), Hull (1988) and Dennett (1993) have deftly paved this way by developing a generic theoretical framework which in principle can be freed from its traditional biological subject matter. More recently, Price (1995) and Price & Shaw (1996) have adapted evolutionary theory to cover 'organizational memetics'. Some readers will be struck by the apparent similarities between books written by students of technology dynamics on co-evolution (Dosi 1984, Nelson & Winter 1982) and the framework embraced in this article. Others who know work on the population ecology of organizations (Hannan & Freeman 1977, 1989) will not fail to see use of a common metaphor either. In some cases, the type of analysis performed by these theoreticians may be quite similar to the view taken here. Though it would be interesting to explore the analogies between these related bodies of theory, it is beyond the scope of this article. The objective here is not to study the evolution of technology or changes in the numbers of various groups of organizations.

In the DoT example, a conceptual monoculture centered around financial profitability and market forces developed. But not in all institutional structures is just one actor able to impose its conceptual frame on all the others. In structures where funds and competences are more evenly spread across the various participants, especially lower tiers of government, other concepts and arguments play a role in discussions and negotiations and are integrated into the applied conceptual systems. In federal Germany, where subnational authorities are undeniable forces in infrastructure planning, the Standardisierte Bewertung (German equivalent of COBA) is a social cost-benefit analysis covering a full range of economic, ecological, scenery, urbanistic and political motives. Lots of less ponderable criteria such as 'spatial quality', 'transport network effects', 'intermodal connections' and 'development of economically weak regions' are explicitly mentioned and valued even when they cannot be quantified.

This definition of 'institutions' is remarkably close to how Dosi and Nelson & Winter view 'technologies'.

From the two distinctions made, the first is quite common: it can be found in what legal theorists and what sociologists view as 'rules' and in organization theory it is also a crucial duo. The second distinction between conceptual and behavioral is much less spread. Simon (1982) mentions the existence of both 'cognitive and institutional rules', whereas Campbell (NIG 1995b) discerns 'interpretative and interactive institutions'. I can very well identify with both.

Sober (1984) dedicates a full chapter of his book to the philosophical meaning of fitness. If being fit means remaining alive after the natural selection, then those who survived turned out to be fit. Such a definition denies the possibility to explain or predict fitness before the selection, leaving it no independent meaning. To be fit is to survive. However, if fitness is defined in terms of physical strength (for living beings) or semantic aptness (for words) increasing the probability of survival, it is no longer tautological. One can have a constitution well-adapted to the environment and still die, one can be a weak exemplar and yet happen to survive. To be fitter is only having a bigger probability to survive.

Theoretically speaking, we could even discern a fourth line of thought (related to the first) claiming that selection happens on populations of genes or populations of concepts (conceptual systems or paradigms). Some genes are more equal than others in the sense that they prestructure the operations of other genes. Equally we could say that some concepts within conceptual systems occupy more central places than others, because they determine the functioning these others have within the system. But whether natural or institutional selection occurs on genes/concepts as such or on geneplexes/conceptual systems was impossible to decide even for the gifted philosophers Toulmin (1972) and Hull (1973).

Institutional evolution takes more time than conceptual evolution. Mutants have to be spread and incorporated into 'brains' and then be translated to new standard and decision rules. New thinking must be transformed into new acting, which puts the power relations in existing interactive institutions at stake: innovators will always find resistance.

It is also promising to relate the concepts embraced here to the work by Hannan & Freeman (1977, 1989), Morgan (1986) and Price (1995) and Price & Shaw (1996) on the evolution of organizations. This will be done in a later article.

MEMES AND THE EXPLOITATION OF IMAGINATION

By
Daniel Dennett

Journal of Aesthetics and Art Criticism, 48, 127-35, Spring 1990.
The David and Miriam Mandel Lecture
American Society for Aesthetics, 47th Annual Meeting, October 27, 1989
New York, NY

The general issue to be addressed in a Mandel Lecture is how (or whether) art promotes human evolution or development. I shall understand the term "art" in its broadest connotations--perhaps broader than the American Society for Aesthetics would normally recognize: I shall understand art to include all artifice, all human invention. What I shall say will *a fortiori* include art in the narrower sense, but I don't intend to draw particular attention to the way my thesis applies to it.

There are few ideas more hackneyed than the idea of the evolution of ideas. It is often said that schools of thought evolve into their successors; in the struggle for attention, the best ideas win, according to the principle of the survival of the fittest, which ruthlessly winnows out the banal, the unimaginative, and the false. Few ideas are more hackneyed--or more abused; almost no one writing about the evolution of ideas or cultural evolution treats the underlying Darwinian ideas with the care they deserve. I propose to begin to remedy that.

The outlines of the theory of evolution by natural selection are now clear: evolution occurs whenever the following conditions exist:

- variation: a continuing abundance of different elements
- heredity or replication: the elements have the capacity to create copies or replicas of themselves
- differential "fitness": the number of copies of an element that are created in a given time varies, depending on interactions between the features of that element (whatever it is that makes it different from other elements) and features of the environment in which it persists. Endnote 1

Notice that this definition, drawn from biology, says nothing specific about organic molecules, nutrition, or even life. It is a more general and abstract characterization of evolution by natural selection. As the zoologist Richard Dawkins has pointed out, the fundamental principle is "that all life evolves by the differential survival of replicating entities" Endnote 2.

The gene, the DNA molecule, happens to be the replicating entity which prevails on our own planet. There may be others. If there are, provided certain other conditions are met, they will almost inevitably tend to become the basis for an evolutionary process.

But do we have to go to distant worlds to find other kinds of replication and other, consequent, kinds of evolution? I think that a new kind of replicator has recently emerged on this very planet. It is staring us in the face. It is still in its infancy, still drifting clumsily about in its primeval

soup, but already it is achieving evolutionary change at a rate which leaves the old gene panting far behind. Endnote 3

These newfangled replicators are, roughly, ideas. Not the "simple ideas" of Locke and Hume (the idea of red, or the idea of round or hot or cold), but the sort of complex ideas that form themselves into distinct memorable units--such as the ideas of

- arch
- wheel
- wearing clothes
- vendetta
- right triangle
- alphabet
- calendar
- the Odyssey
- calculus
- chess
- perspective drawing
- evolution by natural selection
- impressionism
- Greensleeves
- "read my lips"
- deconstructionism

Intuitively these are more or less identifiable cultural units, but we can say something more precise about how we draw the boundaries--about why *D-F#-A* isn't a unit, and the theme from the slow movement of Beethoven's Seventh Symphony is: the units are the smallest elements that replicate themselves with reliability and fecundity. Dawkins coins a term for such units: *memes*--

a unit of cultural transmission, or a unit of *imitation*. 'Mimeme' comes from a suitable Greek root, but I want a monosyllable that sounds a bit like 'gene' . . . it could alternatively be thought of as being related to 'memory' or to the French word *même*.

Examples of memes are tunes, ideas, catch-phrases, clothes fashions, and ways of making pots or of building arches. Just as genes propagate themselves in the gene pool by leaping from body to body via sperm or eggs, so memes propagate themselves in the meme pool by leaping from brain to brain via a process which, in the broad sense, can be called imitation. If a scientist hears, or reads about, a good idea, he passes it on to his colleagues and students. He mentions it in his articles and his lectures. If the idea catches on, it can be said to propagate itself, spreading from brain to brain. Endnote 4

So far, no doubt, this seems to be just a crisp reworking of the standard fare about the evolution and spread of ideas, but in *The Selfish Gene*, Dawkins urges us to take the idea of meme evolution literally. Meme evolution is not just analogous to biological or genetic evolution, not just a process that can be metaphorically described in these evolutionary idioms, but a phenomenon that obeys the laws of natural selection exactly. The theory of evolution by natural

selection is neutral regarding the differences between memes and genes; these are just different kinds of replicators evolving in different media at different rates. And just as the genes for animals could not come into existence on this planet until the evolution of plants had paved the way (creating the oxygen-rich atmosphere and ready supply of convertible nutrients), so the evolution of memes could not get started until the evolution of animals had paved the way by creating a species--*homo sapiens*--with brains that could provide shelter, and habits of communication that could provide transmission media, for memes.

This is a new way of thinking about ideas. It is also, I hope to show, a good way, but at the outset the perspective it provides is distinctly unsettling, even appalling. We can sum it up with a slogan:

A scholar is just a library's way of making another library.

I don't know about you, but I am not initially attracted by the idea of my brain as a sort of dung heap in which the larvae of other people's ideas renew themselves, before sending out copies of themselves in an informational Diaspora. It does seem to rob my mind of its importance as both author and critic. Who is in charge, according to this vision--we or our memes?

There is, of course, no simple answer. We would like to think of ourselves as godlike creators of ideas, manipulating and controlling them as our whim dictates, and judging them from an independent, Olympian standpoint. But even if this is our ideal, we know that it is seldom if ever the reality, even with the most masterful and creative minds. As Mozart famously observed of his own brainchildren:

When I feel well and in a good humor, or when I am taking a drive or walking after a good meal, or in the night when I cannot sleep, thoughts crowd into my mind as easily as you would wish. Whence and how do they come? I do not know and *I have nothing to do with it.* [emphasis added] Those which please me I keep in my head and hum them; at least others have told me that I do so. Endnote 5

Mozart is in good company. Rare is the novelist who *doesn't* claim characters who "take on a life of their own"; artists are rather fond of confessing that their paintings take over and paint themselves, and poets humbly submit that they are the servants or even slaves to the ideas that teem in their heads, not the bosses. And we all can cite cases of memes that persist unbidden and unappreciated in our own minds.

The other day I was embarrassed--dismayed--to catch myself walking along humming a melody to myself: not a theme of Haydn or Brahms or Charlie Parker or even Bob Dylan: I was energetically humming: "It Takes Two to Tango"--a perfectly dismal and entirely unredeemed bit of chewing gum for the ears that was unaccountably popular sometime in the 50's. I am sure I have never in my life chosen this melody, esteemed this melody, or in any way judged it to be better than silence, but there it was, a horrible musical virus, at least as robust in my meme pool as any melody I actually esteem. And now, to make matters worse, I have resurrected the virus in many of you, who will no doubt curse me in days to come when you find yourself humming, for the first time in thirty years, that boring tune.

The first rules of memes, as it is for genes, is that replication is not necessarily for the good of anything; replicators flourish that are good at . . . replicating! -- for whatever reason. As Dawkins has put it,

A meme that made its bodies run over cliffs would have a fate like that of a gene for making bodies run over cliffs. It would tend to be eliminated from the meme-pool. . . . But this does not mean that the ultimate criterion for success in meme selection is gene survival. . . . Obviously a meme that causes individuals bearing it to kill themselves has a grave disadvantage, but not necessarily a fatal one. . . . a suicidal meme can spread, as when a dramatic and well-publicized martyrdom inspires others to die for a deeply loved cause, and this in turn inspires others to die, and so on. Endnote 6

The important point is that there is no *necessary* connection between a meme's replicative power, its "fitness" from *its* point of view, and its contribution to *our* fitness (by whatever standard we judge that). The situation is not totally desperate. While some memes definitely manipulate us into collaborating on their replication *in spite of* our judging them useless or ugly or even dangerous to our health and welfare, many--most, if we are lucky--of the memes that replicate themselves do so not just *with* our blessings, but *because of* our esteem for them. I think there can be little controversy that the following memes are, all things considered, good *from our perspective*, and not just from their own perspective as selfish self-replicators:

Such very general memes as:

- cooperation
- music
- writing
- calendars
- education
- environmental awareness
- arms-reduction
- and such particular memes as:
 - The Prisoner's Dilemma
 - *The Marriage of Figaro*
 - *Moby Dick*
 - long weekends
 - returnable bottles
 - the SALT Treaties
 - undergraduate major

Other memes are more controversial; we can see why they spread, and why, all things considered, we should tolerate them, in spite of the problems they cause for us:

- colorization of classic films
- teaching assistants
- grade point averages

- advertising on television
- *Hustler* magazine

Still others are unquestionably pernicious, but extremely hard to eradicate:

- anti-Semitism
- hijacking airliners
- computer viruses
- spray-can graffiti

Genes are invisible; they are carried by gene-vehicles (organisms) in which they tend to produce characteristic effects ("phenotypic" effects) by which their fates are, in the long run, determined. Memes are also invisible, and are carried by meme-vehicles--pictures, books, sayings (in particular languages, oral or written, on paper or magnetically encoded, etc.) A meme's existence depends on a physical embodiment in some medium; if all such physical embodiments are destroyed, that meme is extinguished. It may, of course, make a subsequent independent reappearance--just as dinosaur genes could, in principle, get together again in some distant future--but the dinosaurs they created and inhabited would not be descendants of the original dinosaurs--or at least not any more directly than we are. The fate of memes--whether copies and copies of copies of them persist and multiply--depends on the selective forces that act directly on the physical vehicles that embody them.

Meme vehicles inhabit our world alongside all the fauna and flora, large and small. By and large they are "visible" only to the human species, however. Consider the environment of the average New York City pigeon, whose eyes and ears are assaulted every day by approximately as many words, pictures, and other signs and symbols as assault each human New Yorker. These physical meme-vehicles may impinge importantly on the pigeon's welfare, but not in virtue of the memes they carry--it is nothing to the pigeon that it is under a page of *The National Inquirer*, not *The New York Times*, that it finds a crumb.

To human beings, on the other hand, each meme-vehicle is a potential friend or foe, bearing a gift that will enhance our powers or a gift horse that will distract us, burden our memories, derange our judgment. We might compare these airborne invaders of our eyes and ears to the parasites that enter our bodies by other routes: there are the beneficial parasites such as the bacteria in our digestive systems without which we could not digest our food, the tolerable parasites, not worth the trouble of eliminating (all the denizens of our skin and scalps, for instance), and the pernicious invaders that are hard to eradicate (the AIDS virus, for instance).

So far, the meme's eye perspective may still appear to be simply a graphic way of organizing very familiar observations about the way items in our cultures affect us, and affect each other. But Dawkins suggests that in our explanations we tend to overlook the fundamental fact that "a cultural trait may have evolved in the way it has simply because it is *advantageous to itself*." [Endnote 7] This is the key to answering the question of whether or not the meme meme is one we should exploit and replicate. There is an unmistakable tension between the meme's-eye view and our normal perspective on the transmission of ideas, and it is time to clarify it.

The normal view is also a normative view: it embodies a canon or ideal about which ideas we ought to "accept" or admire or approve of. (It concentrates on acceptance, rather than transmission and replication; it tends to be individualistic, not communitarian. It is epistemology and aesthetics, not communication theory.) In brief, we ought to accept the true and the beautiful.

In the normal view, the fact that an idea is deemed true or beautiful is sufficient to explain why it is accepted, and the fact that it is deemed false or ugly is sufficient to explain its rejection. These norms are *constitutive*. We require particular explanations of deviations from these norms; their status grounds the air of paradox in such aberrations as "The Metropolitan Museum of Banalities" or "The Encyclopedia of Falsehoods." There is a nice parallel to be found in physics. Aristotelian physics supposed that an object's continuing to move in a straight line required explanation, in terms of something like forces continuing to act on it. Central to Newton's great perspective shift was the idea that such rectilinear motion did *not* require explanation; only deviations from it did--accelerations. We can discern a similar difference in what requires explanation in the two views of ideas. According to the normal view, the following are virtually tautological:

- Idea *X* was believed by the people because *X* was deemed true.
- People approved of *X* because people found *X* to be beautiful.

What requires special explanation are the cases in which, in spite of the truth or beauty of an idea, it is *not* accepted, or in spite of its ugliness or falsehood it *is*. The meme's-eye view purports to be a general alternative perspective from which these deviations can be explained: what is tautological for *it* is

Meme *X* spread among the people because *X* was a good replicator.

Now there is a non-random correlation between the two; it is no accident. We would not survive unless we had a better than chance habit of choosing the memes that help us. Our meme-immunological systems are not foolproof, but not hopeless either. We can rely, as a general, crude, rule of thumb, on the coincidence of the two perspectives: by and large, the good memes are the ones that are also the good replicators.

The theory becomes interesting only when we look at the exceptions, the circumstances under which there is a pulling apart of the two perspectives; only if meme theory permits us better to understand the deviations from the normal scheme will it have any warrant for being accepted. (Note that in its own terms, whether or not the meme replicates successfully is strictly independent of its epistemological virtue; it might spread in spite of its perniciousness, or go extinct in spite of its virtue.)

I need not dwell on the importance of the founding memes for language, and much later, for writing, in creating the infosphere. These are the underlying technologies of transmission and replication analogous to the technologies of DNA and RNA in the biosphere. Nor shall I bother reviewing the familiar facts about the explosive proliferation of these media via the memes for movable type, radio and television, xerography, computers, fax machines, and electronic mail.

Suffice it to say that we are all well aware that we live, today, awash in a sea of paper-borne memes, breathing in an atmosphere of electronically-borne memes.

Memes now spread around the world at the speed of light, and replicate at rates that make even fruit flies and yeast cells look glacial in comparison. They leap promiscuously from vehicle to vehicle, and from medium to medium, and are proving to be virtually unquarantinable. Memes, like genes, are *potentially* immortal, but, like genes, they depend on the existence of a continuous chain of physical vehicles, persisting in the face of the Second Law of Thermodynamics. Books are relatively permanent, and inscriptions on monuments even more permanent, but unless these are under the protection of human conservators, they tend to dissolve in time. As with genes, immortality is more a matter of replication than of the longevity of individual vehicles. The preservation of the Platonic memes, via a series of copies of copies, is a particularly striking case of this. Although some papyrus fragments of Plato's texts roughly contemporaneous with him have been recently discovered, the survival of the memes owes almost nothing to such long-range persistence. Today's libraries contain thousands if not millions of physical copies (and translations) of the *Meno*, and the key ancestors in the transmission of this text turned to dust centuries ago.

Brute physical replication of vehicles is not enough to ensure meme longevity. A few thousand hard-bound copies of a new book can disappear with scarcely a trace in a few years, and who knows how many brilliant letters to the editor, reproduced in hundreds of thousands of copies, disappear into landfills and incinerators every day? The day may come when non-human meme-evaluators suffice to select and arrange for the preservation of particular memes, but for the time being, memes still depend at least indirectly on one or more of their vehicles spending at least a brief, pupal stage in a remarkable sort of meme-nest: a human mind.

Minds are in limited supply, and each mind has a limited capacity for memes, and hence there is a considerable competition among memes for entry into as many minds as possible. This competition is the major selective force in the infosphere, and, just as in the biosphere, the challenge has been met with great ingenuity.

For instance, whatever virtues (from our perspective) the following memes have, they have in common the property of having phenotypic expressions that tend to make their own replication more likely by disabling or pre-empting the environmental forces that would tend to extinguish them: the meme for *faith*, which discourages the exercise of the sort of critical judgment that might decide that the idea of faith was all things considered a dangerous idea [Endnote 8]; the meme for *tolerance* or *free speech*, the meme of including in a chain letter a warning about the terrible fates of those who have broken the chain in the past, the *conspiracy theory* meme, which has a built-in response to the objection that there is no good evidence of the conspiracy: "Of course not--that's how powerful the conspiracy is!" Some of these memes are "good" perhaps and others "bad"; what they have in common is a phenotypic effect that systematically tends to disable the selective forces arrayed against them. Other things being equal, population memetics predicts that conspiracy theory memes will persist quite independently of their truth, and the meme for faith is apt to secure its own survival, and that of the religious memes that ride piggyback on it, in even the most rationalistic environments. Indeed, the meme for faith exhibits *frequency-dependent fitness*: it flourishes particularly in the company of rationalistic memes.

Other concepts from population genetics also transfer smoothly: here is a case of what a geneticist would call *linked loci*: two memes that happen to be physically tied together so that they tend always to replicate together, a fact that affects their chances. There is a magnificent ceremonial march, familiar to us all, and one that would be much used for commencements, weddings, and other festive occasions, perhaps driving "Pomp and Circumstance" and the Wedding March from "Lohengrin" to near extinction, were it not for the fact that its musical meme is too tightly linked to its title meme, which we all tend to think of as soon as we hear the music: Sir Arthur Sullivan's unusable masterpiece, "Behold the Lord High Executioner."

This is actually just a vivid case of one of the most important phenomena in the infosphere: the mis-filtering of memes due to such linkages. We all have filters of the following sort:

Ignore everything that appears in *X*

For some people, *X* is *The National Inquirer* or *Pravda*; for others it is *The New York Review of Books*; we all take our chances, counting on the "good" ideas to make it eventually through the stacks of filters of others into the limelight of our attention.

This structure of filters is itself a meme construction of considerable robustness. John McCarthy, the founder of Artificial Intelligence (or in any event, the coiner of its name, a meme with its own, independent base in the infosphere) once suggested to a humanist audience that electronic mail networks could revolutionize the ecology of the poet. Only a handful of poets can make their living by selling their poems, McCarthy noted, because poetry books are slender, expensive volumes purchased by very few individuals and libraries. But imagine what would happen if poets could put their poems on an international network, where anybody could read them or copy them for a penny, electronically transferred to the poet's royalty account. This could provide a steady source of income for many poets, he surmised. Quite independently of any aesthetic objections poets and poetry lovers might have to poems embodied in electronic media (more to the point: poems displayed in patterns of excited phosphor dots on computer screens), the obvious counter-hypothesis arises from population memetics. If such a network were established, no poetry lover would be willing to wade through thousands of electronic files filled with doggerel, looking for the good poems; there would be a niche created for various memes for poetry-filters. One could subscribe, for a few pennies, to an editorial service that scanned the infosphere for good poems, and different services, with different critical standards, would flourish, as would services for reviewing all the different services--and services that screened, collected, formatted, and presented the works of the best poets in slender electronic volumes which only a few would purchase. The memes for editing and criticism will find niches in any environment in the infosphere; they flourish because of the short supply and limited capacity of minds, whatever the transmission media between minds.

The structure of filters is complex and quick to respond to new challenges, but of course it doesn't always "work". The competition among memes to break through the filters leads to an "arms race" of ploy and counterploy, with ever more elaborate "advertising" raised against ever more layers of selective filters.

Whether this is a good thing or a bad thing depends on your point of view. The huge arrays of garish signs that compete for our attention along commercial strips in every region of the country are the exact counterpart, in the infosphere, of the magnificent redwood forests of the biosphere; if only those redwoods could get together and agree on some sensible zoning restrictions and stop competing with each other for sunlight, they could save all the trouble of building those ridiculous and expensive trunks, stay low and thrifty shrubs, and get just as much sunlight as before! Endnote 9 In the more dignified ecology of academia, the same arms race is manifested in department letterheads, "blind refereeing", the proliferation of specialized journals, book reviews, reviews of book reviews, and anthologies of "classic works".

These filters are not even always intended to preserve the best. Philosophers might care to ask themselves, for instance, how often they are accomplices in increasing the audience for a second-rate article simply because their introductory course needs a simple-minded version of a bad idea that even the freshmen can refute. Some of the most often reprinted articles in twentieth century philosophy are famous precisely because *nobody* believes them; *everybody* can see what is wrong with them. Endnote 10

A related phenomenon in the competition of memes for our attention is *positive feedback*. In biology, this is manifested in such phenomena as the "runaway sexual selection" that explains the long and cumbersome tail of the bird of paradise or the peacock. Dawkins provides an example from the world of publishing: "Best-seller lists of books are published weekly, and it is undoubtedly true that as soon as a book sells enough copies to appear in one of these lists, its sales increase even more, simply by virtue of that fact. Publishers speak of a book "taking off", and those publishers with some knowledge of science even speak of a 'critical mass for take-off'. Endnote 11

The haven all memes depend on reaching is the human mind, but a human mind is itself an artifact created when memes restructure a human brain in order to make it a better habitat for memes. The avenues for entry and departure are modified to suit local conditions, and strengthened by various artificial devices that enhance fidelity and prolixity of replication: native Chinese minds differ dramatically from native French minds, and literate minds differ from illiterate minds. What memes provide in return to the organisms in which they reside is an incalculable store of advantages--with some Trojan horses thrown in for good measure, no doubt. Normal human brains are not all alike; they vary considerably in size, shape, and in the myriad details of connection on which their prowess depends. But the most striking differences in human prowess depend on micro-structural differences (still inscrutable to neuroscience) induced by the various memes that have entered them and taken up residence. The memes enhance each other's opportunities: the meme for education, for instance, is a meme that reinforces the very process of meme-implantation.

But if it is true that human minds are themselves to a very great degree the creations of memes, then we cannot sustain the polarity of vision with which we started; it cannot be "memes versus us" because earlier infestations of memes have already played a major role in determining *who or what we are*. The "independent" mind struggling to protect itself from alien and dangerous memes is a myth; there is, in the basement, a persisting tension between the biological imperative of the genes and the imperatives of the memes, but we would be foolish to "side with"

our genes--that is to commit the most egregious error of pop sociobiology. What foundation, then, can we stand on as we struggle to keep our feet in the memestorm in which we are engulfed? If replicative might does not make right, what is to be the eternal ideal relative to which "we" will judge the value of memes? We should note that the memes for normative concepts--for *ought* and *good* and *truth* and *beauty* are among the most entrenched denizens of our minds, and that among the memes that constitute us, they play a central role. Our existence as us, as what we as thinkers are--not as what we as organisms are--is not independent of these memes.

Dawkins ends *The Selfish Gene* with a passage that many of his critics must not have read:

We have the power to defy the selfish genes of our birth and, if necessary, the selfish memes of our indoctrination. . . . We are built as gene machines and cultured as meme machines, but we have the power to turn against our creators. We, alone on earth, can rebel against the tyranny of the selfish replicators. (p.215.)

In distancing himself thus forcefully from the oversimplifications of pop sociobiology, he somewhat overstates his case. This "we" that transcends not only its genetic creators but also its memetic creators is, I have just claimed, a myth. Dawkins himself seems to acknowledge this in his later work. In *The Extended Phenotype*, Dawkins argues for the biological perspective that recognizes the beaver's dam, the spider's web, the bird's nest as not merely *products* of the phenotype--the individual organism considered as a functional whole--but *parts* of the phenotype, on a par with the beaver's teeth, the spider's legs, the bird's wing. From this perspective, the vast protective networks of memes that we spin is as integral to our phenotypes--to explaining our competences, our chances, our vicissitudes--as anything in our more narrowly biological endowment. Endnote 12 There is no radical discontinuity; one can be a mammal, a father, a citizen, scholar, Democrat, and an associate professor with tenure. Just as man-made barns are an integral part of the barn swallow's ecology, so cathedrals and universities--and factories and prisons--are an integral part of our ecology, as are the memes without which we could not live in these environments.

Homo sapiens have been around for half a million years. The first serious invasion of memes began with spoken language only tens of thousands of years ago, and the second great wave, riding on the meme for writing, is considerably less than ten thousand years in progress--a brief moment in biological time. Since memetic evolution occurs on a time scale thousands of times faster than genetic evolution, however, in the period since there have been memes--only tens of thousands of years--the contributing effects of meme-structures on our constitution--on human phenotypes--vastly outweigh the effects of genetic evolution during that period. So we can answer the defining question of the Mandel Lecture with a rousing affirmative. Does art (in the broad sense) contribute to human evolution? It certainly does, in the most literal sense. In fact, since art appeared on the scene, it has virtually supplanted all other contributions to human evolution. [Endnote 13]

I would like to close with some observations on the history of the meme meme itself, and how its spread was temporarily curtailed. When Dawkins introduced memes in 1976, he described his innovation as a literal extension of the classical Darwinian Theory and so I have treated it here.

Dawkins himself, however, has since drawn in his horns slightly. In *The Blind Watchmaker* (1988), he speaks of an analogy "which I find inspiring but which can be taken too far if we are not careful." (p.196). Later in the same chapter, he says "Cultural 'evolution' is not really evolution at all if we are being fussy and purist about our use of words, but there may be enough in common between them to justify some comparison of principles." (p.216) Why did he retreat like this? Why, indeed, is the meme meme so little discussed thirteen years after *The Selfish Gene* appeared?

In *The Extended Phenotype*, Dawkins replies forcefully to the storm of criticism from sociobiologists, while conceding some interesting but inessential disanalogies between genes and memes--

memes are not strung out along linear chromosomes, and it is not clear that they occupy and compete for discrete 'loci', or that they have identifiable 'alleles'. . . The copying process is probably much less precise than in the case of genes . . . memes may partially blend with each other in a way that genes do not. (p.112)

But then he retreats further, apparently in the face of unnamed and unquoted adversaries:

My own feeling is that its [the meme meme's] main value may lie not so much in helping us to understand human culture as in sharpening our perception of genetic natural selection. This is the only reason I am presumptuous enough to discuss it, for I do not know enough about the existing literature on human culture to make an authoritative contribution to it. (p.112)

I submit that the meme's-eye view of what happened to the meme meme is quite obvious: "humanist" minds have set up a particularly aggressive set of filters against memes coming from "sociobiology," and once Dawkins was identified as a sociobiologist, this almost guaranteed rejection of whatever this interloper had to say about culture--not for good reasons, but just in a sort of immunological rejection. Endnote 14

But look how the meme meme has now infiltrated itself into another, less alien vehicle, a clearly identified, card-carrying academic humanist, a philosopher. In this guise--clothed in a philosopher's sort of words--will it find better chances of replication? I hope so.

My chosen role in this Mandel Lecture has been a humble one, a mere *vector*, a transmitter, with just a few embellishments and mutations, of a meme that has come to play a large role in my mind--large enough, for instance, to determine the content of this lecture. My purpose, after all, has been to create in your minds robust, aggressive copies of various memes that inhabit my mind. I am fairly confident that I have succeeded in that modest goal, and I hope, moreover, that you will forgive me for reviving "It Takes Two to Tango" and be grateful to me for passing on the meme meme.

of Science, 1978, 9, pp. 181-206, both reprinted in E. Sober, ed., *Conceptual Issues in Evolutionary Biology*, 1984, Cambridge, MA: MIT Press.

2. Richard Dawkins, *The Selfish Gene*, Oxford: Oxford University Press, 1976, p.206.

3. ibid

4. ibid

5. Peter Kivy informed me after the Mandel Lecture that this oft-quoted passage is counterfeit--not Mozart at all. I found it in Jacques Hadamard's classic study, *The Psychology of Inventing in the Mathematical Field*, Princeton Univ. Press., 1949, p. 16, and first quoted it myself in "Why the Law of Effect Will Not Go Away," *Journal of the Theory of Social Behaviour*, V, 1975, pp.169-87, reprinted in my book, *Brainstorms*, Cambridge, MA: MIT Press/A Bradford Book, 1978. I persist in quoting it here, in spite of Kivy's correction, because it not only expresses but exemplifies the thesis that memes, once they exist, are independent of authors and critics alike. Historical accuracy is important (which is why I have written this footnote), but the passage so well suits my purposes that I am choosing to ignore its pedigree. I might not have persisted in this, had I not encountered a supporting meme the day after Kivy informed me: I overheard a guide at the Metropolitan Museum of Art, commenting on the Gilbert Stuart portrait of George Washington: "This may not be what George Washington looked like then, but this is what he looks like now."

6. Richard Dawkins, *The Extended Phenotype*, Oxford: W.H. Freeman, 1982, p.110-11.

7. *The Selfish Gene*, p.214.

8. *The Selfish Gene*, p. 212.

9. This, the "tragedy of the commons," deserves a more careful treatment than I can offer on this occasion. Note too that I am submerging a complication that properly should bring our discussion full circle, back to the ideas of Adam Smith about *economic* competition that first inspired Darwin. The competition of the billboards is competition for our attention, but the ulterior goal of acquiring our attention is the seller's goal of acquiring our money, not the meme's goal of replicating itself. The academic examples are not independent of economics, of course, but economics plays a less dominant role, as was ironically acknowledged on a T-shirt worn by a member of the audience at the Mandel Lecture: "Philosophy: I'm in it for the money."

10. The confirmation of this claim is left as an exercise for the reader. Among the memes that structure the infosphere and hence affect the transmission of other memes are the laws of libel.

11. *The Blind Watchmaker*, London: Longman Scientific, 1986, p.219. Dawkins' discussion of these complex phenomena, in the chapter "Explosions and Spirals" (pp. 195-220), is a *tour de force* of explanatory clarity and vividness.

12. In several recent essays I have expanded on the claim that the very structure of our minds is more a product of culture than of the neuroanatomy we are born with: "Julian Jaynes' Software

Archeology," in *Canadian Psychology*, **27**, 1986, pp.149-54; "The Self as the Center of Narrative Gravity," (originally published as "Why we are all novelists," *Times Literary Supplement*, Sept. 16-22, 1988, p.1029), forthcoming in F. Kessel, P. Cole, D. Johnson, eds., *Self and Consciousness: Multiple Perspectives*, Hillsdale, NJ: Erlbaum; "The Evolution of Consciousness," forthcoming in *The Reality Club*, volume 3; and "The Origins of Selves," forthcoming in *Cogito*. See also Nicholas Humphrey and Daniel Dennett, "Speaking For Our Selves: An Assessment of Multiple Personality Disorder," *Raritan*, **9**, 1989, pp.68-98.

13. Those who are familiar with the Baldwin Effect will recognize that art contributes not merely to the fixing of phenotypic plasticity, but can *thereby* change the selective environment and hence hasten the pace of genetic evolution. See my discussion in "The Evolution of Consciousness," *oc.cit.*, and Jonathan Schull, "Are Species Intelligent?" forthcoming in *Behavioral and Brain Sciences*.

14. A striking example of the vituperative and uncomprehending dismissal of Dawkins by a humanist who identifies him as a sociobiologist is found in Mary Midgley, "Gene Juggling," *Philosophy*, **54**, 1979, pp.439-58, an attack so wide of the mark that it should not be read without its antidote: Dawkins' response, "In Defence of Selfish Genes," *Philosophy*, **56**, 1981, pp. 556-73.

MEMES: MYTHS, MISUNDERSTANDINGS, AND MISGIVINGS

By
Daniel C. Dennett

DRAFT for Chapel Hill, October 1998

Richard Dawkins introduced the concept of memes in his 1976 book, *The Selfish Gene*, and the reception for many years was chilly. Then, recently, thanks in part to some energetic campaigning by me on behalf of the meme meme (mainly in *Consciousness Explained* and *Darwin's Dangerous Idea*), the friends of memes began to come out of the woodwork, and a number of books and articles about memes (of varying quality) have begun attracting a second look. Currently the internet blooms with dozens of websites proclaiming the birth of the new science of memetics. Most of this is simply awful, but that should not surprise us. As Sturgeon's Law reminds us, 95% of everything is crap. The hard part--especially during these early days of proto-memetics--is to identify the 5% that is actually good. Sturgeon's Law also suggests, of course, that 95% of the *criticism* of memes and memetics is also crap, so we needn't waste our time rebutting every silly, anxiety-driven objection. My talk will be an attempt to focus on some of the more attention-worthy issues.

1. Perspectives on Cultural Evolution ⁽¹⁾

When one says that cultures evolve, this can be taken as a truism, or as asserting one or another controversial, speculative, unconfirmed theory. Consider a cultural inventory at time t : it includes all the languages, practices, ceremonies, edifices, methods, tools, myths, music, art, and so forth that compose a culture. Over time, the inventory changes. Some items disappear, some multiply, some merge, some change. (When I say some change, I mean to be neutral at this point about whether this amounts to their being replaced by similar items, or their undergoing a transformation.) A verbatim record of this history would not be science; it would be a data base. That is the truism: cultures evolve over time. Now the question remains: how are we to explain the patterns found in that data base? Are there any good theories or models of cultural evolution?

The traditional model to be found in most accounts by historians and anthropologists treats culture as composed of goods, possessions of the people, who husband them in various ways, wisely or foolishly. They carefully preserve their traditions of fire-lighting, house-building, speaking, counting, justice, etc. They trade cultural items as they trade other goods. And of course some cultural items (wagons, pasta, recipes for chocolate cake, etc.) are definitely goods, and we can plot their trajectories using the tools of economics. The people, on this model, are seen as having an autonomous or independent rationality; deprive a person of his goods, and he stands there, naked but rational and full of informed desires. When he clothes himself and arms himself and equips himself with goods, he increases his powers, complicates his desires, etc.

On this way of thinking, the relative "replicative" power of various cultural goods is measured in the marketplace of cost-benefit calculations performed by the people. If Coca Cola bottles proliferate around the world, it is because more and more people prefer to buy a Coke. Advertising may fool them. But then we look to the advertisers, or those who have hired them, to

find the relevant loci of values for our calculations. *Cui bono?* Who benefits? The purveyors of the goods, and those they hire to help them.

Biologists, too, can often make sense of the evolution (in the neutral sense) of features by treating them as goods: one's food, one's nest, one's burrow, one's territory, one's mate[s], one's time and energy. Cost-benefit analyses shed light on the husbandry engaged in by the members of the different species inhabiting some shared environment.⁽²⁾ Not every "possession" is considered a good, however; one's accompanying flies and fleas, the dirt and grime that accumulates on one's body, are of no value, or of negative value, for instance. One's symbionts are not normally considered as goods by biologists, except when the benefits derived from them (by whom?) are manifest.

This perspective is not uniformly illuminating, nor is it obligatory. I would like to suggest that both biologists and economists (and other social scientists) can benefit from adopting a different vantage point on some of these phenomena, one which quite properly gives pride of place to the *Cui bono* question, which can provide alternative answers that are often overlooked. This is Dawkins' meme's-eye point of view, which recognizes--and takes seriously--the possibility that cultural entities may evolve according to selectional regimes that make sense only when the answer to the *Cui bono* question is that it is the cultural items themselves that benefit from the adaptations they exhibit.⁽³⁾

Dawkins' theory of memes, as briefly sketched in a single chapter of *The Selfish Gene* (1976, but see also Dawkins, 1993), is hardly a theory at all, especially compared to the models of cultural evolution developed by other biologists, such as Cavalli-Sforza and Feldman (1981), Lumsden and Wilson (1981), and Boyd and Richerson (1985). Unlike these others, Dawkins offers no formal development, no mathematical models, no quantitative predictions, no systematic survey of relevant empirical findings. But Dawkins does present an idea that is overlooked by all the others, and it is, I think, a most important idea. It is the key to understanding how we can be not just guardians and transmitters of culture, but cultural entities ourselves--all the way in.

Whenever costs and benefits are the issue we need to ask *Cui bono?* A benefit by itself is not explanatory; a benefit in a vacuum is indeed a sort of mystery; until it can be shown how the benefit actually redounds to enhance the replicative power of a replicator, it just sits there, alluring, perhaps, but incapable of explaining anything.

We see an ant laboriously climbing up a stalk of grass. Why is it doing that? Why is that adaptive? What good accrues to the ant by doing that? That is the wrong question to ask. No good accrues to the ant; its brain has been invaded by a fluke (*Dicrocoelium dendriticum*), one of a gang of tiny parasites that need to get themselves into the intestines of a sheep in order to reproduce (Ridley, 1995, p258). (Salmon swim up stream, these parasitic worms drive ants up grass stalks, to improve their chances of being ingested by a passing sheep.) The benefit is not to the reproductive prospects of the ant but the reproductive prospects of the fluke.⁽⁴⁾

Dawkins points out that we can think of cultural items, memes, as parasites, too. Actually, they are more like a simple virus than a worm. Memes are supposed to be analogous to genes, the replicating entities of the cultural media, but they also have vehicles, or phenotypes; they are like

not-so-naked genes. They are like viruses (Dawkins, 1993). As with viruses, there is a phenotype/genotype distinction, but just barely. Basically, a virus is just a string of DNA (or RNA) with attitude. And similarly, a meme is an information-packet (the information, not the vehicle) with attitude--with some phenotypic clothing that has differential effects in the world that thereby influence its chances of getting replicated.

And in the domain of memes, the ultimate beneficiary, the beneficiary in terms of which the final cost-benefit calculations must apply is: the meme itself, not its carriers. This is not to be read as itself a bold empirical claim, ruling out (for instance) the role of individual human agents in devising, appreciating and securing the spread and prolongation of cultural items. It is rather a proposal that we adopt a perspective or point of view, from which a wide variety of different empirical claims can be compared, and the evidence for them considered in a neutral setting, a setting that does not prejudge these hot-button questions.

In the analogy with the fluke, we are invited to consider a meme as like a parasite which commandeers an organism for its own replicative benefit, but we should remember that symbionts can be classified into three fundamental categories:

- *Parasites*, whose presence lowers the fitness of their host
- *Commensals*, whose presence is neutral (though, as the etymology reminds us, they "share the same table"); and
- *Mutualists*, whose presence enhances the fitness of both host and guest

Since these varieties are arrayed along a continuum, the boundaries between them need not be too finely drawn; just where benefit drops to zero or turns to harm is not something to be directly measured by any practical test, though we can explore the consequences of these turning points in models.

The main point to note is that we should expect memes to come in all three varieties, too. This means, for instance, that it is a mistake to assume that the "cultural selection" of a cultural trait is always "for cause"--always because of some perceived (or even misperceived) benefit it provides to the host. We can always ask if the hosts, the human agents that are the vectors, perceive some benefit and (for that reason, good or bad) assist in the preservation and replication of the cultural item in question, but we must be prepared to entertain the answer that they do not. In other words, we must consider as a real possibility the hypothesis that the human hosts are, individually or as a group, either oblivious to, or agnostic about, or even positively dead set against, some cultural item, which nevertheless is able to exploit its hosts as vectors.

The most familiar cases of cultural transmission and evolution discussed are innovations that are obviously of some direct or indirect benefit to the Darwinian--that is, genetic--fitness of the host. A better fishhook catches more fish, feeds more bellies, makes for more surviving grandchildren, etc. The only difference between stronger arms and a better fishhook in the (imagined) calculation of impact on fitness is that the stronger arms might be--might be--passed on quite directly through the germ line, while the fishhook definitely must be culturally transmitted. (The stronger arms could be culturally transmitted as well, of course. A tradition of body-building, for instance, could explain why there was very low [genetic] heritability for strong adult arms, and

yet a very high rate of strong adult arms in a population.) But however it might be that strong arms or fishhooks are transmitted, they are typically supposed to be a good bargain from the perspective of genetic fitness. The bargain might, however, be myopic--only good in the short run. After all, even agriculture, in the long run, may be a dubious bargain if what you are taking as your summum bonum is Darwinian fitness (see Diamond, 1997, for fascinating reflections on the uncertain benefits of abandoning the hunter-gatherer lifestyle). What alternatives are there?

First, we need to note that in the short run (evolutionarily speaking--that is, from the perspective of a few centuries or even millennia) something might flourish independently of whether it was of actual benefit to genetic fitness, but strongly linked to whether it was of *apparent* benefit to genetic fitness. Even if you think that Darwinian fitness enhancement is the principle driving engine of cultural evolution, you have to posit some swifter, more immediate mechanism of retention and transmission. It's not hard to find one. Cultural items may exploit machinery that had earned its keep in the past by embodying a fitness-enhancing set of preferences. We are genetically endowed with a quality space in which some things feel good and some things don't, and we tend to live by the rule: *if it feels good, keep it*. This rough and ready rule can be tricked, of course. The sweet tooth is a standard example. The explosion of cultural items--artifacts, practices, recipes, patterns of agriculture, trade routes--that depend quite directly on the exploitation of the sweet tooth has probably had a considerable net negative effect on human genetic fitness. Notice that explaining the emergence of these cultural items by citing their "apparent" benefit to genetic fitness does not in any way commit us to the (preposterous) claim that people think (mistakenly) that they are enhancing their genetic fitness by acquiring and consuming sugar. The rationale is not theirs, but Mother Nature's. They just go with what they like.

Still, given what they like, they choose rationally, and indeed ingeniously and often with impressive foresight, how to obtain what they like. This is still the traditional model of cultural evolution, with agents husbanding their goods in order to maximize what they prefer--and getting their preferences quite directly from their genetic heritage. A more interesting possibility is acquiring new preferences that are themselves culturally transmitted symbionts of one sort or another. Each will have to bootstrap itself into the memosphere by exploiting some pre-established preference, but this recursive process, which can proceed at breakneck speed relative to the glacial pace of genetic evolution, can transform human agents indefinitely far away from their genetic beginnings. In an oft-quoted passage, E. O. Wilson claimed otherwise: The genes hold culture on a leash. The leash is very long, but inevitably values will be constrained in accordance with their effects on the human gene pool. (Wilson, 1978, p167)

This leash, I am claiming, is indefinitely long, in the sense that the constraints Wilson speaks of can be so co-opted, exploited, and obtunded in a recursive cascade of cultural products and meta-products that it is not clear that there are any points in imaginable cultural design space that could not, in principle, be occupied by some product that could ultimately be traced back, via Wilson's leash of historical processes, to the genes. Many of these imaginable points would no doubt be genetic culs-de-sac (H. sapiens would sooner or later go extinct as a result of occupying those points), but this is no barrier to their evolving in the swift time of cultural history.⁽⁵⁾

Not only can we acquire tastes; we can acquire meta-tastes. That is, we can discover in the

culture, and thereupon adopt, a taste for "cultivating" further acquired tastes, and so forth. At each stage we can anticipate finding parasites, commensals and mutualists--but we can classify these only by asking the *Cui bono?* question against a new background and making one local determination or another. One person's scholarly connoisseurship is another person's addiction to trash. Meta-memes for "traveling" or "being a collector" or "having a hobby" or "educating oneself" can themselves be viewed as either exploiters or enhancers of the pre-established personal (no longer genetic) preferences. It is interesting that in common parlance we often call our preferences "weaknesses,"--as in "I have a weakness for strong cheese (or puns or redheads)"--deftly implying a standard to which in the same breath we deny any personal allegiance.

And this, then, is the main point I wanted to emphasize in Dawkins' vision. The memes that proliferate will be the memes that replicate by hook or by crook. Think of them as entering the brains of culture members, making phenotypic alterations thereupon, and then submitting themselves to the great selection tournament--not the Darwinian genetic fitness tournament (life is too short for that) but the Dawkinsian meme-fitness tournament. It is their fitness as memes that is on the line, not their host's genetic fitness, and the environments that embody the selective pressures that determine their fitness are composed in large measure of other memes.

Why do their hosts put up with this? Why should the overhead costs of establishing a whole new system of differential reproduction be borne by members of *H. sapiens*? Note that the question to be asked and answered here is parallel to the question we ask about any symbiont-host relationship: why do the hosts put up with it? And the short answer is that it is too costly to eradicate, but this just means that the benefits accruing to the machinery that is being exploited by the parasites are so great that keeping the machinery and tolerating the parasites (to the extent that they are tolerated) has so far been the best deal available. And whether or not in the long run (millions of years) this infestation will be viewed as mutualism or commensalism or parasitism, in the short run (the last few millennia) the results have been spectacular: the creation of a new biological type of entity: a person.

I like to compare this development to the arrival of the eukaryotes more than a billion years ago. Relatively simple prokaryotes got invaded by some of their neighbors, and the resulting endosymbiotic teams were more fit, and prospered, enabling a biological revolution. The eukaryotes, living alongside their prokaryotic cousins, but enormously more complex, versatile and competent, opened up the design space of multi-cellular organisms. Similarly, the emergence of culture-infected hominids has opened up yet another region of hitherto unoccupied and untraversable design space. We live alongside our animal cousins, but we are enormously more complex, versatile and competent. And by joining forces with our memes, we create new candidates for the locus of benefit, new answers to *Cui bono?*

2. Two all too standard Objections

One often hears it said that the ways in which cultural entities evolve are profoundly un-Darwinian. Two claims in particular, are often presented as if they carried the day: cultural evolution, unlike Darwinian evolution, is "Lamarckian," and cultural evolution, unlike Darwinian evolution, is replete with "horizontal transmission"--that is to say, design elements

can hop freely from lineage to lineage, not bound by the requirements of heredity. Once reptiles and mammals have gone their separate ways, reptile innovations cannot jump to mammals, but only to descendant reptiles, but this restriction does not exist in cultural evolution. I have sometimes wondered why we don't hear more about a third disanalogy: cultural ideas don't reproduce sexually--mama and papa ideas getting it on to make little baby ideas of both genders. Probably we don't hear it because it would wear its disingenuousness on its sleeve--a lazy (or desperate) stab at something that would excuse one from having to think further about the prospects of a Darwinian account of culture. *Sexual* reproduction is not, after all, an obligatory element of Darwinian evolution; surely 99% of all the Darwinian evolution that has ever occurred on this planet was among asexually reproducing replicators, and however large sexuality looms now, it is itself an evolved feature, not a precondition for Darwinian evolution. So the absence of sexual reproduction in the memosphere is no challenge to neo-Darwinian explanation. But exactly the same point can be made about the purported disanalogies of Lamarckianism and horizontal transmission or anastomosis (lineage-joining).

Let's consider Lamarckianism first. Neo-Darwinian orthodoxy, since Weissman, declares that characteristics acquired through use cannot be transmitted genetically to one's progeny. Darwin himself, notoriously, was quite happy to countenance this feature of Lamarckianism, but he has long been deemed in error. Weissman's distinction between germ line--roughly, eggs and sperm-- and somatic line cells--all the rest--has proven itself over and over, and the doctrine that there are no avenues by which somatic line innovations could enter the germ line is indeed a textbook verity, although various exotic possibilities have been seriously discussed in the literature, and arguably exist in some restricted quarters. But notice that this, the orthodox, way of identifying Lamarckian phenomena (as things that don't happen) applies crisply only to multi-cellular organisms. What counts as a Lamarckian phenomenon in the world of bacteria, archaea, or in the world of viruses? In the case of a virus, which I have described as just a string of DNA with attitude, the line between soma and germ line is non-existent. Something that changes the structure of an individual virus string can be called a genotypic change--a mutation--if it is passed on in replication, and otherwise a mere phenotypic change. It is not that such a line can't be drawn, but it becomes a line that prohibits nothing. The claim that Lamarckianism has been vindicated in the world of viral evolution would thus be Pickwickian. And since memes are no more multicellular than they are sexual, the fact that there is no clear way---no "principled" way, as they used to say at MIT--of distinguishing mutations from phenotypic acquisitions hardly shows that they are disqualified from a neo-Darwinian treatment.⁽⁶⁾ Most--much more than 99%-- of the life forms on this planet have evolved under just such a regime, and neo-Darwinism certainly covers their evolution handily.

And the same verdict applies to anastomosis, although this is a recent and ill-appreciated discovery: there is lots of horizontal transmission in protist and bacterial evolution--a fact that plays hob with attempts to define separate bacterial lineages in a "principled" way--and once again, the bulk of the evolution on the planet has been amongst just such tiny bits. Once we shift our focus away from our own multicellular, sexually reproducing lineages to the more numerous lineages on the planet, these standard objections lose much if not all their force. Memes are indeed not very much like elephant genomes, but so what?

3. But what about human reason--and creativity? ⁽⁷⁾

A confusion that misdirects the imagination of theorists in another direction derives, I suspect, from a subtle misreading of Darwin's original use of artificial selection (deliberate animal breeding) and "unconscious" selection (the unwitting promotion of favored offspring of domesticated animals) as bridges to his concept of natural selection. While it is true that Darwin wished to contrast the utter lack of foresight or intention in natural selection with the deliberate goal-seeking of the artificial selectors, in order to show how the natural process could in principle proceed without any mentality at all, he did not thereby establish (as many seem to have supposed) that deliberate, goal-directed, intentional selection is not a sub variety of natural selection! The short legs of dachshunds, and the huge udders of Holsteins are just as much products of natural selection as the wings of the eagle; they just evolved in an environment that included a particularly well-focused selective pressure consisting of human agents. These phenotypes fall under the same laws of transmission genetics, the same replicator dynamics, as any others--as special and extreme cases in which the default "randomness" or noisiness of selective pressure has been greatly reduced.

Applied to cultural evolution, the implication is this: There is no conflict between the claim that artifacts (including abstract artifacts--memes) are the products of natural selection, and the claim that they are (often) the foreseen, designed products of intentional human activity. It appears that some thinkers in the newly emerging school of *evolutionary archeology* have made this mistake. According to a critique by Boone and Smith (1998), at least some evolutionary archeologists think that the only way to be hardheaded and scientific about the Darwinian evolution of culture is to deny all intention, all rationality, on the part of human culture-makers. They opt for "selection rather than decision-making" [p11]. That is simply a mistake, for the same reason it would be a mistake to say that the fancy plumage of prize pigeons is the result of decision-making rather than selection. But Boone and Smith fall in the same trap, in their discussion of the interesting phenomenon of the spread of snowmobiles among the Cree in northern Canada. They are surely right that the adoption of snowmobiles by the Cree cannot be accounted for in terms of the differential biological replication of the snowmobile users, but they misread the more interesting meme's-eye view perspective. They say:

The alternative that 'snowmobile memes' were transmitted more effectively than 'snowshoe memes' to non-descendant Cree (as well as offspring), while plausible, is not natural selection [emphasis added]; more significantly, it requires precisely the kind of adaptive decision-making that EA [evolutionary archeology] is dedicated to eliminating from archeological explanation. [Ms P12]

On the contrary, if you adopt the meme's-eye perspective, in which the snowmobile meme is seen as the replicator, with its own fitness, then cultural evolution can be seen to be due to "adaptive decision-making" while also a variety of natural selection. Consider the fitness of the domesticated horses that spread so quickly among the Native Americans after their introduction, but then more recently, after the advent of the automobile, have dwindled sharply. These fluctuations in genetic fitness have been due to changes in the selective forces arrayed in the various environments in which the horses have existed, of course, and the fact that conscious,

foresightful human agents form the key component in those selective environments does nothing to remove the phenomena from the domain of standard genetic evolution by natural selection.

Among those who have overlooked this fact is Steven Pinker, who dismisses models of cultural evolution in a brief passage in *How the Mind Works* (1997):

Stop being so literal-minded! respond the fans of cultural evolution. Of course cultural evolution is not an exact replica of the Darwinian version. In cultural evolution, the mutations are directed and the acquired characteristics are inherited. Lamarck, while being wrong about biological evolution, turned out to be right about cultural evolution. To say that cultural evolution is Lamarckian is to confess that one has no idea how it works. The striking features of cultural products, namely their ingenuity, beauty, and truth (analogous to organisms' complex adaptive design), come from the mental computations that "direct"--that is, invent--the "mutations," and that "acquire"--that is, understand--the "characteristics." (1997, p209)

Pinker has imputed the wrong parallel; it is not Lamarck's model, but Darwin's model of artificial selection (as a special case of natural selection) that accommodates the phenomena he draws to our attention in this passage. And it is ironic that Pinker overlooks this, since the cultural phenomena he himself has highlighted as examples of evolution-designed systems, linguistic phenomena, are almost certainly not the products of foresightful, ingenious, deliberate human invention. Some designed features of human languages are no doubt genetically transmitted, but many others--such as changes in pronunciation, for instance--are surely culturally transmitted, and hence products of cultural, not genetic, evolution.

Some memes are like domesticated animals; they are prized for their benefits, and their replication is closely fostered and relatively well understood by their human owners. Some memes are more like rats; they thrive in the human environment in spite of being positively selected against--ineffectually--by their unwilling hosts. And some are more like bacteria or other viruses, commandeering aspects of human behavior (provoking sneezing, for instance) in their "efforts" to propagate from host to host. There is artificial selection of "good" memes--like the memes of arithmetic and writing, which are carefully taught to each new generation. And there is unconscious selection of memes of all sorts--like the subtle mutations in pronunciation that spread through linguistic groups, presumably with some efficiency advantage, but perhaps just hitchhiking on some quirk of human preference. And there is unconscious selection of memes that are positively a menace, but which prey on flaws in the human decision-making apparatus, as provided for in the genome and enhanced and adjusted by other cultural innovations--such as the abducted-by-aliens meme, which makes perfect sense when its own fitness as a cultural replicator is considered. Only the meme's-eye perspective unites all these possibilities under one view.⁽⁸⁾

Finally, one of the most persistent sources of discomfort about memes is the dread suspicion that an account of human minds in terms of brains being parasitized by memes will undermine the precious traditions of human creativity. On the contrary, I think it is clear that *only* an account of creativity in terms of memes has much of a chance of giving us any way to *identify with* the products of our own minds. We human beings extrude other products, on a daily basis, but after infancy, at any rate, we don't tend to view our feces with the pride of an author or artist. These

are mere biological byproducts, and although they have their own modest individuality and idiosyncrasy, it is not anything we cherish. How could we justify viewing the secretions of our poor infected brains with any more pride? Because we *identify with* some subset of the memes we harbor. Why? Because among the memes we harbor are those that put a premium on identifying with just such a subset of memes! Lacking that meme-borne attitude, we would be mere *loci* of interaction, but we have such memes--that is who we are.

4. Conclusion

This spectrum of possibilities, from the unwitting, unconscious hosting of culture-borne viruses (of all "attitudes") to the foresightful design and promulgation of inventions and creations that intelligently and artfully draw upon well-understood cultural resources, must be viewable under a single, unifying perspective. It is only from such a perspective that we can make sense of the trajectories that have taken us--and only us--beyond the horizons of our selfish genes, by creating new environments of selection--persons and their projects--that in turn create utterly unprecedented answers to the *Cui bono?* question. Such a view of cultural evolution doesn't deny the possibility of moving to what might be called a *mind's-eye* perspective of evaluation; it is precisely what makes such a transition--without any help from skyhooks--possible.

2. Such organisms need not be deemed to be making conscious decisions, of course, but the rationality, such as it is, of the "decisions" they make is typically anchored to the expected benefit to the individual organism. See Sober and Wilson (1998) for important discussions of gene, individual, and group benefits of such decision-making.

3. Sober and Wilson (1998) note that there is a gap in their model of cultural evolution: "We can say that functionless [relative to human individual and group fitness] behavior should be more common in humans than other species, but we cannot explain why a particular functionless behavior has evolved in a particular culture. That kind of understanding probably requires detailed historical knowledge of the culture, and it may turn out that some behaviors evolved mainly by chance." p171.

4. Strictly speaking, to the reproductive prospects of the fluke's genes (or the fluke's "group"'s genes), for as Sober and Wilson (1998) point out (p18) in their use of *D. dendriticum* as an example of altruistic behavior, the fluke that actually does the driving in the brain is a sort of kamikaze pilot, who dies without any chance of passing on its own genes, benefiting its [asexually reproduced] near-clones in other parts of the ant.

5. Boyd and Richerson (1992) show that "Virtually *any* behavior can become stable within a social group if it is sufficiently buttressed by social norms." (Sober and Wilson, 1998, p.152)

6. In fact in most of the brief, shallow discussions of the Lamarckian nature of cultural evolution that I have seen, it is never made clear which entities were deemed capable of transmitting acquired characteristics. Sometimes, I suspect, the objector had dimly in mind the strictly irrelevant fact that human *hosts* can transmit to other human hosts cultural items that they themselves had acquired during their lifetimes. That is not Lamarckianism at all.

7. This section is adapted from Dennett, 1998.

8. The meme's-eye perspective offers many other points of theoretical leverage, but those are topics for another occasion.

THE EVOLUTION OF CULTURE

By
Daniel C. Dennett

The Charles Simonyi Lecture
Oxford University, Feb 17, 1999

The philosopher Daniel C. Dennett is interested in consciousness, and his view of it, similar to that of Minsky's, is as high-level, abstract thinking. He is known as the leading proponent of the computational model of the mind; he has clashed with philosophers such as John Searle who maintain that the most important aspects of consciousness — intentionality and subjective quality — can never be computed. He is the philosopher of choice of the AI community. In his more recent work, he has turned to what he calls "Darwin's dangerous idea"; he is squarely in the ultra-Darwinist camp of George C. Williams and Richard Dawkins, and he has with great energy mustered a serious critique of the scientific ideas of Stephen Jay Gould. "Dan Dennett is our best current philosopher," says Marvin Minsky. "He is the next Bertrand Russell. Unlike traditional philosophers, Dan is a student of neuroscience, linguistics, artificial intelligence, computer science, and psychology. He's redefining and reforming the role of the philosopher." — John Brockman

Cultures evolve. In one sense, this is a truism; in other senses, it asserts one or another controversial, speculative, unconfirmed theory of culture. Consider a cultural inventory of some culture at some time--say 1900AD. It should include all the languages, practices, ceremonies, edifices, methods, tools, myths, music, art, and so forth, that compose that culture. Over time, that inventory changes. Today, a hundred years later, some items will have disappeared, some multiplied, some merged, some changed, and many new elements will appear for the first time. A verbatim record of this changing inventory through history would not be science; it would be a data base. That is the truism: cultures evolve over time. Everybody agrees about that. Now let's turn to the controversial question: how are we to explain the patterns to be found in that data base? Are there any good theories or models of cultural evolution?

1. Science or Narrative?

One possibility is that the only patterns to be found in cultural evolution defy scientific explanation. They are, some might want to say, *narrative* patterns, not scientific patterns. There is clearly something to this, but it won't do as it stands, for many scientific patterns are also historical patterns, and hence are revealed and explained in narratives--of sorts. Cosmology, geology, and biology are all historical sciences. The great biologist D'Arcy Thompson once said:

Everything is the way it is because it got that way.

If he is right--if *everything* is the way it is because it got that way--then every science must be, in part, a historical science. But not all history--all recounting of events in temporal sequence-- is *narrative*, some might want to say. Human history is unique in that the patterns it exhibits require a different *form* of understanding: *hermeneutical* understanding or *Verstehen*, or--you can

count on the Germans to have lots of words for claims like this--*Geisteswissenschaft* (approximately: spiritual science). I think this too is partly right; there *is* a particular sort of understanding that is used to make sense of narratives about human agents. It is also true that the mark of a *good* story is that its episodes unfold *not* as the predicted consequences of general laws and initial conditions, but in delightfully surprising ways. These important facts do not show, however, that cultural evolution escapes the clutches of science and must be addressed in some other realm of inquiry. Quite the contrary; the humanistic comprehension of narratives and the scientific explanation of life processes, for all their differences of style and emphasis, have the same logical backbone. We can see this by examining the special form of understanding we use when following--and creating--good narratives.

Mediocre narratives are either a pointless series of episodes in temporal order--just "one damn thing after another"--or else so utterly predictable as to be boring. Between randomness and routine lie the good stories, whose surprising moments make sense in retrospect, in the framework provided by the unsurprising moments. The perspective from which we can understand these narratives is what I have called *the intentional stance*: the strategy of analyzing the flux of events into *agents* and their (rational) *actions* and *reactions*. Such agents--people, in this case--*do things for reasons*, and can be predicted--up to a point--by cataloguing their reasons, their beliefs and desires, and calculating what, given those reasons, the most rational course of action for each agent would be. Sometimes the most rational course is flat obvious, so while the narrative is predictive (or true), it is uninteresting and unenlightening. To take a usefully simple case, a particular game of chess is interesting to the extent that we are surprised by either the brilliant moves that outstrip our own calculations of what it would be rational to do, or the blunders, which we thought too sub-optimal to predict.

In the wider world of human activity, the same holds true. We don't find the tale of Jane going to the supermarket on her way home from work interesting precisely because it all unfolds so predictably from the intentional stance; today she never encountered any interesting options, given her circumstances. Other times, however, the most rational thing for an agent to do is far from obvious, and maybe practically incalculable. When we encounter these narratives, we are surprised (and sometimes delighted, sometimes appalled) by the actual outcome. It makes sense in retrospect, but who'd have guessed that she'd decide to do *that*? The vast mass of routinely rational human behavior doesn't make good novels, but it is just such humdrum rational narrative that provides the background pattern that permits us to make sense, retrospectively, of the intriguing vagaries we encounter, and to anticipate the complications that will arise when the trains of events they put in motion collide.

The traditional model used by historians and anthropologists to try to explain cultural evolution uses the intentional stance as its explanatory framework. These theorists treat culture as composed of goods, possessions of the people, who husband them in various ways, wisely or foolishly. People carefully preserve their traditions of fire-lighting, house-building, speaking, counting, justice, etc. They trade cultural items as they trade other goods. And of course some cultural items (wagons, pasta, recipes for chocolate cake, etc.) are definitely goods, and so we can plot their trajectories using the tools of economics. It is clear from this perspective that highly prized cultural entities will be protected at the expense of less favored cultural entities, and there will be a competitive market where agents both "buy" and "sell" cultural wares. If a

new method of house-building or farming or a new style of music sweeps through the culture, it will be because people perceive advantages to these novelties.

The people, on this model, are seen as having an autonomous rationality: deprive a person of his goods, and he stands there, naked but rational and full of informed desires. When he clothes himself and arms himself and equips himself with goods, he increases his powers, complicates his desires. If Coca Cola bottles proliferate around the world, it is because more and more people prefer to buy a Coke. Advertising may fool them. But then we look to the advertisers, or those who have hired them, to find the relevant agents whose desires fix the values for our cost-benefit calculations. *Cui bono?* Who benefits? The purveyors of the goods, and those they hire to help them. etc. On this way of thinking, then, the relative "replicative" power of various cultural goods--whether Coke bottles, building styles or religious creeds--is measured in the marketplace of cost-benefit calculations performed by the people.

Biologists, too, can often make sense of the evolution (in the neutral sense) of features of the natural world by treating them as goods belonging to various members of various species: one's food, one's nest, one's burrow, one's territory, one's mate[s], one's time and energy. Cost-benefit analyses shed light on the husbandry engaged in by the members of the different species inhabiting some shared environment.[1] Not every "possession" is considered a good, however. The dirt and grime that accumulates on one's body, to say nothing of the accompanying flies and fleas, are of no value, or of negative value, for instance. These hitchhikers are not normally considered as goods by biologists, except when the benefits derived from them (by *whom?*) are manifest.

This traditional perspective can obviously explain many features of cultural and biological evolution, but it is not uniformly illuminating, nor is it obligatory. I want to show how theorists of culture--historians, anthropologists, economists, psychologists, and others--can benefit from adopting a different vantage point on these phenomena. It is a different application of the intentional stance, one which still quite properly gives pride of place to the *Cui bono* question, but which can provide alternative answers that are often overlooked. The perspective I am talking about is Richard Dawkins' *meme's-eye point of view*, which recognizes--and takes seriously--the possibility that cultural entities may evolve according to selectional regimes that make sense only when the answer to the *Cui bono* question is that it is the cultural items *themselves* that benefit from the adaptations they exhibit. [2]

2. Memes as Cultural Viruses

Whenever costs and benefits are the issue we need to ask *Cui bono?* A benefit by itself is not explanatory; a benefit in a vacuum is indeed a sort of mystery; until it can be shown how the benefit actually redounds to enhance the replicative power of a replicator, it just sits there, alluring, perhaps, but incapable of explaining anything.

We see an ant laboriously climbing up a stalk of grass. Why is it doing that? Why is that adaptive? What good accrues to the ant by doing that? That is the wrong question to ask. No good at all accrues to the ant. Is it just a fluke, then? In fact, that's exactly what it is: a fluke! Its brain has been invaded by a fluke (*Dicrocoelium dendriticum*), one of a gang of tiny parasites

that need to get themselves into the intestines of a sheep in order to reproduce (Ridley, 1995, p258). (Salmon swim up stream, these parasitic worms drive ants up grass stalks, to improve their chances of being ingested by a passing sheep.) The benefit is not to the reproductive prospects of the ant but the reproductive prospects of the fluke. [3]

Dawkins points out that we can think of cultural items, memes, as parasites, too. Actually, they are more like a simple virus than a worm. Memes are supposed to be analogous to genes, the replicating entities of the cultural media, but they also have vehicles, or phenotypes; they are like not-so-naked genes. They are like viruses (Dawkins, 1993). Basically, a virus is just a string of nucleic acid with attitude--and a protein overcoat. A viroid is an even more naked gene. And similarly, a meme is an information-packet with attitude--with some phenotypic clothing that has differential effects in the world that thereby influences its chances of getting replicated. (What is a meme *made of*? It is made of information, which can be carried in *any* physical medium. More on this later.)

And in the domain of memes, the ultimate beneficiary, the beneficiary in terms of which the final cost-benefit calculations must apply is: the meme itself, not its carriers. This is not to be heard as a bold empirical claim, ruling out (for instance) the role of individual human agents in devising, appreciating and securing the spread and prolongation of cultural items. As I have already noted, the traditional perspective on cultural evolution handsomely explains many of the patterns to be observed. My proposal is rather that we adopt a perspective or point of view from which a wide variety of different empirical claims can be compared, *including the traditional claims*, and the evidence for them considered in a neutral setting, a setting that does not prejudge these hot-button questions.

In the analogy with the fluke, we are invited to consider a meme to be like a parasite which commandeers an organism for its own replicative benefit, but we should remember that such hitchhikers or *symbionts* can be classified into three fundamental categories:

- *Parasites*, whose presence lowers the fitness of their host;
- *Commensals*, whose presence is neutral (though, as the etymology reminds us, they "share the same table"); and
- *Mutualists*, whose presence enhances the fitness of both host and guest.

Since these varieties are arrayed along a continuum, the boundaries between them need not be too finely drawn; just where benefit drops to zero or turns to harm is not something to be directly measured by any practical test, though we can explore the consequences of these turning points in models.

We should expect memes to come in all three varieties, too. This means, for instance, that it is a mistake to assume that the "cultural selection" of a cultural trait is always "for cause"--always because of some perceived (or even misperceived) benefit it provides to the host. We can always ask if the hosts, the human agents that are the *vectors*, perceive some benefit and (for that reason, good or bad) assist in the preservation and replication of the cultural item in question, but we must be prepared to entertain the answer that they do not. In other words, we must consider as a real possibility the hypothesis that the human hosts are, individually or as a group, either

oblivious to, or agnostic about, or even positively dead set against, some cultural item, which nevertheless is able to exploit its hosts as vectors.

The most familiar cases of cultural transmission and evolution--the cases that tend to be in the spotlight--are innovations that are obviously of some direct or indirect benefit to the genetic fitness of the host. A better fishhook catches more fish, feeds more bellies, makes for more surviving grandchildren, etc. The only difference between stronger arms and a better fishhook in the (imagined) calculation of impact on fitness is that the stronger arms might be passed on quite directly through the germ line, while the fishhook definitely must be culturally transmitted. (The stronger arms *could* be culturally transmitted as well. A tradition of body-building, for instance, could explain why there was very low [genetic] heritability for strong adult arms, and yet a very high rate of strong adult arms in a population.) But however it might be that strong arms or fishhooks are transmitted, they are typically supposed to be a good bargain from the perspective of genetic fitness. The bargain might, however, be myopic--only good in the short run. After all, even agriculture, in the long run, may be a dubious bargain if what you are taking as your *summum bonum* is Darwinian fitness (see Diamond, 1997, for fascinating reflections on the uncertain benefits of abandoning the hunter-gatherer lifestyle). What alternatives are there?

First, we need to note that in the short run (evolutionarily speaking--that is, from the perspective of a few centuries or even millennia) something might flourish in a culture independently of whether it was of actual benefit to genetic fitness, but strongly linked to whether it was of *apparent* benefit to genetic fitness. Even if you think that Darwinian fitness enhancement is the principle driving engine of cultural evolution, you have to posit some swifter, more immediate mechanism of retention and transmission. It's not hard to find one. We are genetically endowed with a biased quality space: some things feel good and some things don't. We tend to live by the rule: *if it feels good, keep it*. This rough and ready rule can be tricked, of course. The sweet tooth is a standard example. The explosion of cultural items--artifacts, practices, recipes, patterns of agriculture, trade routes--that depend quite directly on the exploitation of the sweet tooth has probably had a considerable net *negative* effect on human genetic fitness. Notice that explaining the emergence of these cultural items by citing their "apparent" benefit to genetic fitness does not in any way commit us to the claim that people think that they are enhancing their genetic fitness by acquiring and consuming sugar. The rationale is not theirs, but Mother Nature's. They just go with what they like.

Still, given what people innately like, they go on to figure out, ingeniously and often with impressive foresight, how to obtain what they like. This is still the traditional model of cultural evolution, with people husbanding their goods in order to maximize what they prefer--and getting their preferences quite directly from their genetic heritage. But this very process of rational calculation can lead to more interesting possibilities. As such an agent complicates her life, she will almost certainly acquire new preferences that are themselves culturally transmitted symbionts of one sort or another. Her sweet tooth may lead her to buy a cookbook, which inspires her to enroll in a culinary arts program, which turns out to be so poorly organized that she starts a student protest movement, in which she is so successful that she is invited to head an educational reform movement, for which a law degree would be a useful credential, and so on. Each new goal will have to bootstrap itself into the memosphere by exploiting some pre-established preference, but this recursive process, which can proceed at breakneck speed relative

to the glacial pace of genetic evolution, can transform human agents indefinitely far away from their genetic beginnings. In an oft-quoted passage, E. O. Wilson claimed otherwise: The genes hold culture on a leash. The leash is very long, but inevitably values will be constrained in accordance with their effects on the human gene pool. (Wilson, 1978, p167)

But Wilson's leash is indefinitely long and elastic. Consider the huge space of *imaginable* cultural entities, practices, values. Is there any point in that Vast space that is utterly unreachable? Not that I can see. The constraints Wilson speaks of can be so co-opted, exploited, and blunted in a recursive cascade of cultural products and meta-products that there may well be traversable paths to every point in that space of imaginable possibilities. I am suggesting, that is, that cultural possibility is less constrained than genetic possibility. We can articulate persuasive biological arguments to the effect that certain imaginable species are unlikely in the extreme--flying horses, unicorns, talking trees, carnivorous cows, spiders the size of whales--but neither Wilson nor anybody else to my knowledge has yet offered parallel grounds for believing that there are similar obstacles to trajectories in imaginable cultural design space. Many of these imaginable points in design space would no doubt be genetic cul-de-sacs, in the sense that any lineage of *H. sapiens* that ever occupied them would eventually go extinct as a result, but this dire prospect is no barrier to the evolution and adoption of such memes in the swift time of cultural history. [4] To combat Wilson's metaphor with one of my own: the genes provide not a leash but a launching pad, from which you can get almost anywhere, by one devious route or another. It is precisely in order to explain the patterns in cultural evolution that are *not* strongly constrained by genetic forces that we need the memetic approach.

The memes that proliferate will be the memes that replicate one way or another--by hook or by crook. Think of them as entering the brains of culture members, making phenotypic alterations thereupon, and then submitting themselves to the great selection tournament--not the Darwinian genetic fitness tournament (life is too short for that) but the Dawkinsian meme-fitness tournament. It is their fitness as memes that is on the line, not their host's genetic fitness. And the environments that embody the selective pressures that determine their fitness are composed in large measure of other memes.

Why do their hosts put up with this? Why should the overhead costs of establishing a whole new system of differential reproduction be borne by members of *H. sapiens*? Note that the question to be asked and answered here is parallel to the question we ask about any symbiont-host relationship: why do the hosts put up with it? And the short answer is that it is too costly to eradicate, but this just means that the benefits accruing to the machinery that is being exploited by the parasites are so great that keeping the machinery and tolerating the parasites (to the extent that they are tolerated) has so far been the best deal available. And whether or not in the long run (millions of years) this infestation will be viewed as mutualism or commensalism or parasitism, in the short run (the last few millennia) the results have been spectacular: the creation of a new biological type of entity: a person.

I like to compare this development to the revolution that happened among the bacteria roughly a billion years ago. Relatively simple *prokaryotes* got invaded by some of their neighbors, and the resulting *endosymbiotic* teams were more fit than their uninfected cousins, and prospered. These *eukaryotes*, living alongside their prokaryotic cousins, but enormously more complex, versatile

and competent thanks to their hitchhikers, opened up the design space of multi-cellular organisms. Similarly, the emergence of culture-infected hominids has opened up yet another region of hitherto unoccupied and untraversable design space. We live alongside our animal cousins, but we are enormously more complex, versatile and competent. Our brains are bigger, to be sure, but it is mainly due to their infestation by memes that they gain their powers. Joining forces with our own memes, we create new candidates for the locus of benefit, new answers to *Cui bono?*

3. Darwin's Path to Memetic Engineering

The meme's-eye view doesn't just open up new vistas for the understanding of patterns in culture; it also provides the foundation for answering a question left dangling by the traditional model of cultural evolution. The traditional view presupposes rational self-interested agents, intent on buying and selling, and improving their lot. *Where did they come from?* The standard background assumption is that they are just animals, whose *Cui bono?* question is to be dealt with in terms of the impact on genetic fitness, as we have seen. But when people acquire other interests, including interests directly opposed to their genetic interests, they enter a new space of possibilities--something no salmon or fruitfly or bear can do. How could this great river of novelty get started?

Here I think we can get help from Darwin's opening exposition of the theory of natural selection. In the first chapter of *Origin of Species*, Darwin introduces his great idea of natural selection by an ingenious expository device, an instance of the very gradualism that he was about to discuss. He begins not with natural selection--his destination--but what he calls *methodical selection*: the deliberate, foresighted, intended "improvement of the breed" by animal and plant breeders. He begins, in short, with familiar and uncontroversial ground that he can expect his readers to share with him.

We cannot suppose that all the breeds were suddenly produced as perfect and as useful as we now see them; indeed, in several cases, we know that this has not been their history. The key is man's power of accumulative selection: nature gives successive variations; man adds them up in certain directions useful to him. [p30, Harvard facsimile edn]

But, he goes on to note, in addition to such methodical selection, there is another process, which lacks the foresight and intention, which he calls *unconscious selection*:

At the present time, eminent breeders try by methodical selection, with a distinct object in view, to make a new strain or sub-breed, superior to anything existing in the country. But, for our purpose, a kind of Selection, which may be called Unconscious, and which results from every one trying to possess and breed from the best individual animals, is more important. Thus, a man who intends keeping pointers naturally tries to get as good dogs as he can, and afterwards breeds from his own best dogs, but he has no wish or expectation of permanently altering the breed. [p34].

Long before there was deliberate breeding, unconscious selection was the process that created and refined all our domesticated species, and even at the present time, unconscious selection

continues. Darwin gives a famous example:

There is reason to believe that King Charles's spaniel has been unconsciously modified to a large extent since the time of that monarch. [p35]

There is no doubt that unconscious selection has been a major force in the evolution of domesticated species. On unconscious selection of both domesticated plants and animals, see Jared Diamond, *Guns, Germs and Steel*. In our own time, unconscious selection goes on apace, and one ignores it at our peril. Unconscious selection in bacteria and viruses for resistance to antibiotics is only the most notorious and important example. Consider the "genes for longevity" that have recently been bred into laboratory animals such as mice and rats. It is probably true, however, that much if not all of the effect that has been obtained in these laboratory breeding experiments has simply undone the unconscious selection for short-livedness at the hands of the suppliers of those laboratory animals. The stock the experimenters started with had shorter life expectancy than their wild cousins simply because they had been bred for many generations for early reproductive maturity, and robustness, and short lives came along as an unintended (unconscious) side consequence (Daniel Promislow, personal correspondence).

Darwin pointed out that the line between unconscious and methodical selection was itself a fuzzy, gradual boundary:

The man who first selected a pigeon with a slightly larger tail, never dreamed what the descendants of that pigeon would become through long-continued, partly unconscious and partly methodical selection. [p 39]

And both unconscious and methodical selection, he notes finally, are but special cases of an even more inclusive process, natural selection, in which the role of human intelligence and choice stands at zero. From the perspective of natural selection, changes in lineages due to unconscious or methodical selection are merely changes in which one of the most prominent selective pressures in the environment is human activity. It is not restricted, as we have seen, to domesticated species. White-tailed deer in New England now seldom exhibit the "white flag" of a bobbing tail during headlong flight that was famously observed by early hunters; the arrival of human beings today is much more likely to provoke them to hide silently in underbrush than to flee. Those white flags were too easy a target for hunters with guns, it seems.

This nesting of different processes of natural selection now has a new member: genetic engineering. How does it differ from the methodical selection of Darwin's day? It is just less dependent on the pre-existing variation in the gene pool, and proceeds more directly to new candidate genomes, with less overt and time-consuming trial and error. Darwin had noted that in his day,

Man can hardly select, or only with much difficulty, any deviation of structure excepting such as is externally visible; and indeed he rarely cares for what is internal. [p38].

But today's genetic engineers have carried their insight into the molecular innards of the organisms they are trying to create. There is ever more accurate foresight, but even here, if we

look closely at the practices in the laboratory, we will find a large measure of exploratory trial and error in their search of the best combinations of genes.

We can use Darwin's three levels of genetic selection, plus our own fourth level, genetic engineering, as a model for four parallel levels of *memetic* selection in human culture. In a speculative spirit, I am going to sketch how it might go, using an example that has particularly challenged some Darwinians, and hence been held up as a worthy stumbling block: a cultural treasure untouchable by evolutionists: music. Music is unique to our species, but found in every human culture. It is manifestly complex, intricately designed, an expensive consumer of time, energy and materials. How did music start? What was or is the answer to its *Cui bono* question? Steven Pinker (1997) is one Darwinian who has recently declared himself baffled about the possible evolutionary origins and survival of music, but that is because he has been looking at music in the old-fashioned way, looking for music to have some contribution to make to the genetic fitness of those who make and participate in the proliferation of music. [5] There may well be some such effect that is important, but I want to make the case that there might also be a purely *memetic* explanation of the origin of music. Here, then, is my Just-so Story, working gradually up Darwin's hierarchy of kinds of selection.

Natural selection of musical memes

One day one of our distant hominid ancestors sitting on a fallen log happened to start banging on with a stick--*boom boom boom*. For *no good reason at all*. This was just idle diddling, a byproduct, perhaps, of a slightly out-of-balance endocrine system. This was, you might say, mere nervous fidgeting, but the repetitive sounds striking his ears just happened to feel to him like a slight improvement on silence. A feedback loop was closed, and the *repetition--boom boom boom--*was "rewarding". If we leave this individual all by himself, drumming away on his log, then we would say that he had simply developed a habit, *possibly* therapeutic in that it "relieved anxiety," but just as possibly a *bad* habit--a habit that did him and his genes no good at all, but just exploited a wrinkle that happened to exist in his nervous system, creating a feedback loop that tended to lead to individual replications of drumming by him under various circumstances. No musical appreciation, no insight, no goal or ideal or project need be imputed to our solitary drummer.

Now introduce some other ancestors who happen to see and hear this drummer. They might pay no attention, or be irritated enough to make him stop or drive him away, or they might, again *for no reason*, find their imitator-circuits tickled into action; they might feel an urge to drum along with musical Adam. What are these imitator circuits I've postulated? Just whatever it takes to make it somewhat more likely than not that some activities by conspecifics are imitated, a mere reflex if you like--of which we may see a fossil trace when spectators at a football match cannot help making shadow kicking motions more or less in unison with the players on the field. One can postulate reasons why having some such imitative talents built-in would be a valuable adaptation--one that enhances one's genetic fitness--but while this is both plausible and widely accepted, it is strictly speaking unnecessary for my Just-so Story. The imitative urge might just as well be a functionless byproduct of some other adaptive feature of the human nervous system. Suppose, then, that for no good reason at all, the drumming habit is *infectious*. When one hominid starts drumming, soon others start drumming along in imitation. This could happen. A

perfectly pointless practice, of no utility or fitness-enhancing benefit at all, could become established in a community. It might be positively detrimental: the drumming scares away the food, or uses up lots of precious energy. It would then be just like a disease, spreading simply because it *could* spread, and lasting as long as it could find hosts to infect. If it was detrimental in this way, variant habits that were less detrimental--less virulent--would tend to evolve to replace it, other things being equal, for they would tend to find more available healthy hosts to migrate to. And of course such a habit *might* even provide a positive benefit to its hosts (enhancing their reproductive chances--a familiar dream of musicians everywhere, and it might be true, or have been true in the past). But providing a genetic benefit of this sort is only one of the paths such a habit might pursue in its mindless quest for immortality. Habits--good, bad and indifferent--could persist and replicate, unappreciated and unrecognized, for an indefinite period of time, provided only that the replicative and dispersal machinery is provided for them. The drumming virus is born.

Let me pause to ask the question: what is such a habit made of? What gets passed from individual to individual when a habit is copied? Not stuff, not packets of material, but pure information, the information that generates the pattern of behavior that replicates. A cultural virus, unlike a biological virus, is not tethered to any particular physical medium of transmission. [6]

Unconscious selection of memes

On with our Just-so Story. Some of the drummers begin to hum, and of all the different hums, a few are more infectious than the rest, and those hominids who happen to start the humming in these ways become the focus of attention, as sources of humming. A competition between different humming patterns emerges. Here we can begin to see the gradual transition to unconscious selection. Suppose that being such a focus of humming happens to feel good--whether or not it enhances one's genetic fitness slightly (it might, of course; perhaps the females tend to be more receptive to those who start the winning hums). The same transition to unconscious selection can be seen among viruses and other pathogens, by the way. If scratching an itch feels good, and also has the side effect of keeping a ready supply of viral emigrés on one's fingertips, the part of the body most likely to come in contact with another host, one is unconsciously selecting for just such a mode of transmission by one's myopic and uncomprehending preference for scratching when one itches--and this does not depend on scratching having any fitness-enhancing benefits *for you*: it may be, like the ant's hankering for the top of the grass stem, a desire that benefits the parasite, not the host. Similarly, if varying tempo and pitch of one's hums feels good, and also happens to create a ready supply of more attention-holding noises for spreading to conspecifics, one's primitive aesthetic preference can begin to shape, unconsciously, the lineages of humming habit that spread through one's community.

Brains in the community begin to be infected by a variety of these memes. Competition for time and space in these brains becomes more severe. The infected brains begin to take on a structure, as the memes that enter "learn" to cooperate on the task of turning a brain into a proper memene, with lots of opportunities for entrance and exit (and hence replication). [7] Meanwhile, any

memes out there "looking for" hosts, will have to compete for available space therein. Just like germs.

Methodical Selection of memes

As the structure grows, it begins to take on a more active role in selecting. That is to say, the brains of the hosts, like the brains of the owners of domesticated animals, become ever more potent and discerning selective agencies--still largely unwitting, but nevertheless having a powerful influence. Some people, it turns out, are better at this than others. As Darwin says of animal breeders,

Not one man in a thousand has accuracy of eye and judgment sufficient to become an eminent breeder. P32.

We honor Bach, the artistic genius, but he was no "natural" doodler, an intuitive genius just "playing by ear". He was the master musical technologist of his day, the inheritor of musical instruments that had had their designs honed over several millennia, as well as some relatively recent additions to the music-maker's toolbox--a fine system of musical notation, keyboard instruments that permitted the musician to play many notes at once, and an explicit, codified, rationalized *theory* of counterpoint. These mind-tools were revolutionary in the way they opened up musical design space for Bach and his successors.

And Bach, like the one man in a thousand who has the discernment to be an eminent animal breeder, knew how to breed new strains of music from old. Consider, for instance, his hugely successful chorale cantatas. Bach shrewdly chose, for his breeding stock, *chorales*--hymn melodies that had already proven themselves to be robust inhabitants of their human hosts, *already domesticated* tunes his audiences had been humming for generations, building up associations and memories, memes that had already sunk their hooks deeply into the emotional habits and triggers of the brains where they had been replicating for years. Then he used his technology to create variations on these memes, seeking to strengthen their strengths and damp their weaknesses, putting them in new environments, inducing new hybrids.

Memetic Engineering

What about memetic engineering? Was Bach, in virtue of his highly sophisticated approach to the design of replicable musical memes, not just a *meme-breeder* but a *memetic engineer*? In the light of Darwin's admiring comment on the rare skill--the genius--of the good breeder, it is interesting to note how sharply our prevailing attitudes distinguish between our honoring the "art" of selective breeding and our deep suspicion and disapproval of the "technology" of gene-splicing. Let's hear it for *art*, but not for *technology*, we say, forgetting that the words share a common ancestor, *techné*, the Greek word for art, skill, or craft in any work. We retreat in horror from genetically engineered tomatoes, and turn up our noses at "artificial" fibers in our clothing, while extolling such "organic" and "natural" products as whole grain flour or cotton and wool, forgetting that grains and cotton plants and sheep are themselves products of human technology, of skillful hybridization and rearing techniques. He who would clothe himself in fibers

unimproved by technology and live on food from non-domesticated sources is going to be cold and hungry indeed.

Besides, just as genetic engineers, for all their foresight and insight into the innards of things, are still at the mercy of natural selection when it comes to the fate of their creations (that is why, after all, we are so cautious about letting them release their brainchildren on the outside world), so too the memetic engineer, no matter how sophisticated, still has to contend with the daunting task of winning the replication tournaments in the memosphere. One of the most sophisticated musical memetic engineers of the age, Leonard Bernstein, wryly noted this in a wonderful piece he published in 1955 entitled:

"Why don't you run upstairs and write a nice Gershwin tune?"
(*New York Times*, April 1955 Reprinted in *The Joy of Music*, 1959, pp52-62)

Bernstein had credentials and academic honors aplenty in 1955, but no songs on the Hit Parade.

A few weeks ago a serious composer-friend and I . . . got boiling mad about it. Why shouldn't we be able to come up with a hit, we said, if the standard is as low as it seems to be? We decided that all we had to do was to put ourselves into the mental state of an idiot and write a ridiculous hillbilly tune.

They failed--and not for lack of trying. As Bernstein wistfully remarked, "It's just that it would be nice to hear someone accidentally whistle something of mine, somewhere, just once." [p54]

His wish came true, of course, a few years later in 1961, when *West Side Story* burst into the memosphere.

4. Conclusions

There is surely much, much more to be said--to be discovered--about the evolution of music. I chose it as my topic because it so nicely illustrates the way the traditional perspective on culture and the evolutionary perspective can join forces, instead of being seen to be in irresolvable conflict. If you believe that music is *sui generis*, a wonderful, idiosyncratic feature of our species that we prize in spite of the fact that it has *not* been created to enhance our chances of having more offspring, you may well be right--*and if so, there is an evolutionary explanation of how this can be true*. You cannot evade the obligation to explain how such an expensive, time-consuming activity came to flourish in this cruel world, and a Darwinian theory of culture is an ally, not an opponent, in this investigation.

While it is true that Darwin wished to contrast the utter lack of foresight or intention in natural selection with the deliberate goal-seeking of the artificial or methodical selectors, in order to show how the natural process could in principle proceed without any mentality at all, he did not thereby establish (as many seem to have supposed) that deliberate, goal-directed, intentional selection is not a subvariety of natural selection! There is no conflict between the claim that

artifacts (including abstract artifacts--memes) are the products of natural selection, and the claim that they are (often) the foreseen, designed products of intentional human activity.

Some memes are like domesticated animals; they are prized for their benefits, and their replication is closely fostered and relatively well understood by their human owners. Some memes are more like rats; they thrive in the human environment in spite of being positively selected against--ineffectually--by their unwilling hosts. And some are more like bacteria or viruses, commandeering aspects of human behavior (provoking sneezing, for instance) in their "efforts" to propagate from host to host. There is artificial selection of "good" memes--like the memes of arithmetic and writing, the theory of counterpoint, and Bach's cantatas, which are carefully taught to each new generation. And there is unconscious selection of memes of all sorts--like the subtle mutations in pronunciation that spread through linguistic groups, presumably with some efficiency advantage, but perhaps just hitchhiking on some quirk of human preference. And there is unconscious selection of memes that are positively a menace, but which prey on flaws in the human decision-making apparatus, as provided for in the genome and enhanced and adjusted by other cultural innovations--such as the abducted-by-aliens meme, which makes perfect sense when its own fitness as a cultural replicator is considered. Only the meme's-eye perspective unites all these possibilities under one view.

Finally, one of the most persistent sources of discomfort about memes is the dread suspicion that an account of human minds in terms of brains being parasitized by memes will undermine the precious traditions of human creativity. On the contrary, I think it is clear that *only* an account of creativity in terms of memes has much of a chance of giving us any way to *identify with* the products of our own minds. We human beings extrude other products, on a daily basis, but after childhood, we don't tend to view our feces with the pride of an author or artist. These are mere biological byproducts, and although they have their own modest individuality and idiosyncrasy, it is not anything we cherish. How could we justify viewing the secretions of our poor infected brains with any more pride? Because we *identify with* some subset of the memes we harbor. Why? Because among the memes we harbor are those that put a premium on identifying with just such a subset of memes! Lacking that meme-borne attitude, we would be mere *loci* of interaction, but we have such memes--that is who we are.

COMPETING MEMES ANALYSES

By

dirlamd@bellsouth.net

Abstract

Aunger (2000) and Edmonds (2002) argue that memetics is a theory without a methodology, in imminent danger of dying from lack of novel interpretations and empirical work. Edmonds challenges memeticists to conduct empirical tests. This article presents Competing Memes Analysis, an empirical methodology that can readily be applied to significant social problems. The methodology is implemented in three steps. Step 1 identifies the organization of memes within an activity. Each activity is assumed to exhibit numerous small groups of memes where each meme within a group competes with all other memes in the group and can be combined with any meme from any other group. The succession of memes that occurs with increasing experience can be a powerful clue to identifying competing memes. Step 2 collects records of activities and codes them for the presence or absence of each meme identified in Step 1. Any activity that people acquire from each other by imitation can be readily coded for the presence or absence of competing memes. Step 3 analyzes changing frequencies of each coded meme over time or space. Models of these changes can give useful clues to suggest empirical studies that will provide important social and scientific results. Ecology's Lotka-Volterra model of competing species illustrates the usefulness to memetics of population models.

Keywords: memetic methodology, meme, drawing, writing, scientific research, Lotka-Volterra, competition

1. The challenge to memetics

Aunger (2000) contains several arguments that memetics is a theory without a methodology. He concludes (p. 230) "The ultimate test—which would preempt theoretical objections—is whether memetics can produce novel empirical work or insightful interpretations of previous results. It has not yet done so, but must do so in the near future. Otherwise, it is likely that memetics will be perceived to be a misguided enterprise. The clock is ticking."

Edmonds (2002) extends Aunger's argument by specifying three challenges for memetics. His first challenge is for a conclusive case study which shows a cultural process that (a) exhibits faithful replication where the replication process is transferred to many sources and (b) passes through a large enough quantity of such transfers to show adaptation resulting from verifiable advantages and consistent with current population-genetics models. He suggests nursery rhymes and legal phrases as appropriate test cases. Edmonds' second challenge is for a falsifiable theory that identifies when a memetics interpretation is appropriate and necessary. Edmonds' third

challenge is for a credible simulation of an emergent (not "designed in") memetic process, analogous to "exhibiting a simulation of the emergence of life from the interaction of chemicals." This paper describes methodological techniques for meeting Edmonds' case-study and memetics-interpretation challenges. Before describing the methodology it would be helpful to clarify a few aspects of the memetics challenge.

1.1 General and specific memetics

A significant source of potential confusion about memetics resembles the confusion within scientific history that occurred with Kuhn's (1969) initial conception of "paradigm." A paradigm referred both to (a) "the entire constellation of beliefs, values, techniques and so on shared by members of a given community" and also to (b) "the concrete puzzle-solutions which...replace explicit rules as a basis for the solution of the remaining puzzles of normal science." Note that the second, specific conception enables the former general conception and thus is the deeper of the two.

Similarly, memetics is used in both a general and a specific manner. Specifically, we have the model of actions or artifacts that can be imitated with fidelity, fecundity and durability. Generally, we have the conception of memes as actions or artifacts that evolve independently of the people producing them. The specific conception enables the general one and is the deeper. But just like there are a host of biological studies that rely on but do not discuss evolutionary processes, there are also a host of possible memetics studies that rely on but do not discuss evolutionary processes. Furthermore, the methods used in general memetics studies may be directly applicable to the fundamental questions raised within the specific conception. This occurs especially when studies have a methodological rather than a theoretical focus. Thus, a vast array of ecological, geological and genetic models depends on genetic evolution without addressing it and many mathematical models in these fields preceded evolutionary models by decades. The power of evolutionary thinking was due as much to the remarkable convergence of knowledge that supported it as to its own models. It seems likely that a future principle of the memetics of science will be that converging knowledge is a necessary predecessor to the dominance of any scientific system.

1.2 Edmonds' First Challenge: The Case Study

Critical to Edmonds' argument is that passing his challenges would show the "usability" of memetics. Edmonds' suggestion of nursery rhymes and legal phrases as apt test cases was based on the assumption that the examples were "of a limited nature about which good quality data is available." More ambitious studies would not be believed until such "straightforward" examples had been established.

Case studies are certainly essential, but Edmonds' suggested topics can be improved. Unambitious content by no means guarantees straightforward conduct and interpretation of any study. The failure of attempts to program translation, transcription, and even textual search belie the straightforwardness of any natural language task. Especially at this early point in memetics research, the methodology and interpretation of all studies will be questioned. The critical factor for the future of memetics is not straightforward conduct and interpretation. Rather, the critical

factor is whether the questions lead the scientific community to ignore or use and debate the results. The potential for use and debate, rather than obscurity, varies directly with the author's skill, the author's community support and the significance of the topic. Furthermore, the dynamics of the transmission of memes will be affected by the importance of the topic. Observing natural memetic transmission and adaptation is likely to be far more difficult for small niche topics, like those Edmonds suggested, than for topics that have more urgent and widespread social content. A primary goal of this paper is to show that although the quick-fix case study does not exist, there are methods that make the consequential studies no more difficult than those with minimal importance.

1.3 Edmonds' Second Challenge: The falsifiable theory of when to use memetics

In his challenge for a falsifiable theory of when to use memetics, Edmonds rightly argues for a biological advantage of large brains independent to the hosting of memes. The issue of deciding when to apply memetics arguments, however, might be better conceived as methodological than theoretical. Though a theory might be easier to apply to ongoing social change, researchers would benefit more from operational definitions. Once several operational definitions have become established, the common elements would point to the needed theory.

The ideal, operational definition would involve direct observation of imitation. Short of that ideal, indirect studies could use situations involving developmental or historical change that (a) minimize the influence of intra-individual processes and (b) allow for a high level of opportunity for imitation. One way of precluding intra-individual processes is to study only a single record per person. A high level of opportunity for imitation occurs by examining situations that contain a high probability of frequent contact between persons being studied.

2. Competing Memes Analysis

Competing Memes Analysis is a method that makes studies of consequential topics no more difficult than those with minimal importance. It is a three step process that

- (1) organizes activities into groups of competing memes that often emerge in developmental successions,
- (2) codes records of activities for the presence or absence of each meme, and
- (3) constructs models of the changing frequencies of the memes.

The methodology has been constructed through studies of the ontogenetic development of drawing (Dirlam, 1996, contains a preliminary analysis), writing (Dirlam, 1982), and the historical development of research methods in developmental psychology (Dirlam, Gamble, and Lloyd, 1999). The purpose of the drawing and writing studies was to design objective pedagogical alternatives to educational testing that could be used with natural products of classroom activities. The purpose of the study of research methods was to determine whether the analytical models that fit the ontogeny of drawing and writing also fit historical development.

2.1. Creating multidimensional classifiers from successions of memes

The first step in the Competing Memes Analysis of an activity is to create multidimensional classifiers of competing memes (Dirlam, 1980). Each activity is assumed to exhibit numerous small groups of memes each of which comprises a dimension. A group of memes is a dimension when each meme within the group competes with all other memes in it and can be combined with any meme from any other group (see Appendix A for an example). The succession of memes that occurs with increasing experience can be a powerful clue to identifying competing groups. A memetic classifier for an activity consists of several dimensions of memes.

Memetic classifiers can be readily constructed by anyone with modest expertise in a topic. A straight forward approach is to observe differences between people performing the activity who have various levels of experience. When one approach to the activity is commonly replaced by another, the two approaches are competing memes. Sometimes the later appearing memes contain earlier appearing ones. In any case, since the memes can be defined to be mutually exclusive, each succession becomes a dimension.

Dimensions can and should be defined as exhaustive by generalizing to include all other cases in the definition of one meme within each dimension. Thus, every record of an activity being investigated is assigned to one meme within each group of competing memes. When an emerging meme becomes frequent enough to separate from a generalized meme, it will be necessary to redefine and recode the dimension. Analysis of large collections of records might also reveal that some memes are so rare that they should be logically combined with others. Experts in an activity can help to construct definitions of each meme so that coders can reliably distinguish which is being used. For most important activities, there is theoretical literature that suggests a rich variety of memes. For example, more than half of the dimensions of competing memes used in the study of developmental research methods mentioned above were based on concepts from Danziger (1990). The memetic classifier for the study is presented in Appendix A. The study involved coding 912 articles written from 1930 to 1992 for the presence or absence of each meme in the classifier.

The number of dimensions in a competing memes analysis is a matter of researcher choice and depends on the state of knowledge in the subject at the time of the study. It should be noted, however, that gathering and examining records is usually much harder than coding them. Therefore, studies with several dimensions require considerably less resources per dimension than single-dimension studies. The memes themselves are like fractals—they can apply to content as fine-grained as words, lines and study locations or as general as complete discourses, complete drawings and complete research articles.

2.2. Collecting and coding records

The second step in Competing Memes Analysis is to systematically collect and code records of memes. In order to permit the construction of testable models, the records should be drawn from a corpus that contains a meaningful point in time or space for all samples. For example, time points for the studies of drawing and writing were the age of each participant and time points for

the developmental research study were the publication years of the articles. Studying the spread of memes from their spatial points of origin should also generate rich, useful results. Drawings are self-contained records of the actions of those who made them. Similarly, writing samples record the actions of writers and research reports record the actions of researchers. Audio and video tapes are also records of memetic activity. Because memes are imitated, any user of a meme and many non-users can identify uses of it by others. This means that discrete samples can be reliably coded for the presence or absence of a meme. If a ten-dimensional system has been defined (as in section 2.1 above), each record will contain ten memes.

One clear implication of memetics is that humans are uniquely capable of identifying memes. The only rival species, apes and parrots, are readily surpassed in speed, variety and complexity of imitation by preschool children. Examining the diversity of memes in the three studies that have used Competing Memes Analysis reveals that the complexity or importance of memes did not affect our ability to identify them. Hence, consequential studies are no more difficult than those with minimal importance.

2.3. Modeling frequency changes over time or space

Once records have been coded, it is possible to count the uses of memes in situations with important consequences, whether they be economic (e.g., the use of a new product), social (e.g., the spread of juvenile crime), political (e.g., the repetition of a candidate's message), educational (e.g., the way students and programs are evaluated) or scientific (e.g., the spread of a methodology). For example in the study of developmental research methods, the model projected that the growth of difference statistics was so fast that if a competitor did not emerge in the next few decades, data analysis would consume so much of available resources (i.e. social acceptance) that it would implode (see Figure 1). During the 1930-1992 study period, data modeling was too rare to analyze separately from difference statistics. But since it is a valued and slow-growing alternative, it is a possible solution to the collapse of the analysis dimension.

Figure 1. Best fitting Lotka-Volterra model for competing data analysis memes

Memetics skeptics would most readily accept studies that operationally define their memetic nature by setting up situations for observing imitation. However, imitation can be inferred rather than directly observed, and can be interpreted broadly as reproduction. This opens up the potential to use archival data (e.g. research reports, crime incident reports, corporate audits and so forth). A dramatic memetics success would occur if memes were discovered that effectively competed with such practices as crime among low income juveniles, self and community destructiveness among religious fundamentalists and fraud among corporate CEOs faced with poor results. Key evidence for successful competition would come from changing frequencies of memes over time or space.

Beyond identifying memes, Competing Memes Analysis may involve a search for

- (1) the path of succession from one meme to the next,
- (2) the resources required,
- (3) the growth rate and
- (4) the competitive strength of such practices.

Results of these types of studies may help us to understand such issues as

- (a) how memes that are seen as "weeds" contribute to general survival and
- (b) how the harmful effects of overgrowth of such memes can be controlled.

An example of (a) would be marketing processes that make it possible to establish products in extremely competitive markets, but permit monopoly-like overgrowth in noncompetitive markets. Examples of (b) would be finding competitors to the emergence of monopolies ranging from antitrust laws to innovations that disrupt them. The problems solved while undertaking a rich variety of such studies could provide the sort of clarity needed to meet Edmonds' challenge for a falsifiable theory of when to use memetics.

Definitive answers to questions about resources, growth rate and competitive strength may be difficult to obtain without detailed experimental studies. However, once hundreds of records of memes have been systematically collected from a population, placed within a meaningful distribution of time or space, coded and counted, it is possible to develop models of the frequency changes. Such models can reveal characteristics of memes that are difficult to observe directly. They also make detailed, testable predictions.

A model that influenced the competing memes analysis, proposed here, is the Lotka-Volterra model of species competition (see Appendix B). This model describes the population of species that compete within an ecosystem as depending on four parameters: the initial population, the maximum sustainable population, the growth rate, and the competitive strength. Given these parameter values, at least four life cycles of memes can be identified (see Appendix A). Rapid growth rate is high enough to create chaotic fluctuations in a noncompetitive environment. Data

analysis modeled in Figure 1 is an example. High competitive strength reduces the rapid growth of competitors to moderate levels or less.

Life cycles	Parameter values		
	Initial prevalence	Growth rate	Competitive strength
Default	High	Near zero	Near zero
Niche	Low	Slow	High
Pioneering	Low	Rapid	Low
Dominant	Low	Moderate	High

Table 1. Lotka-Volterra values for four memetic life cycles

Once such vital statistics of a group of memes have been worked out, scientifically significant and socially valuable experiments can be conducted to determine the factors that influence the long-term vitality of particular memes. For example, revisiting the species analogy, we note that pioneering species are often those that adapt to the presence of many predators by growing very rapidly. If such species find an environment where the predators are absent, their populations can grow so rapidly that they consume too much for the environment to sustain them. The formerly adaptive high growth results in a local extinction. It takes little imagination to realize what powerful social consequences would occur when the analogous process operates mimetically. Pioneering growth may be as essential to responding to social threats or establishing new products as it is to establish species in predatory environments. But planners need to be aware of the social or economic danger that these new responses or products pose if their memetic competitors were to suddenly vanish.

In conclusion, Competing Memes Analysis provides memetics with a method for conducting precise studies of memetic processes found in any human activity. It can be summarized as a 3 step process. Step 1 identifies the organization of memes within an activity. Each activity is assumed to exhibit numerous small groups of memes where each meme within a group competes with all other memes in the group and can be combined with any meme from any other group. The succession of memes that occurs with increasing experience can be a powerful clue to identifying competing groups. Step 2 collects records of activities and codes them for the presence or absence of each meme identified in Step 1. Step 3 analyzes changing frequencies of each coded meme over time or space. Models of these changes can give useful clues to suggest empirical studies that will provide important social and scientific results.

Appendix A: Memetic system for the historical development of developmental research

DIMENSIONS	Life cycles (see Table 1 for explanation of life cycles)			
	Default	Niche	Pioneering	Dominant
DEPENDENT VARIABLES What was measured in the study?	Limited Behaviors Easily counted, or Categorized Coded free behavior	Summed or Enumerated Standardized tests or sums of ratings of loosely connected items)		Categorized and Other coded free behavior combined with a second dependent variable
DATA ANALYSIS What kind of statistics were used?		Descriptive Statistics like counts, means or correlations	Difference Statistics t-tests, ANOVAs non-parametric difference tests or modeling	
DESIGNS How often were comparable measurements taken?	One Session Per Task	Micro-longitudinal Repeated measurements taken weeks apart	Longitudinal Repeated measurements taken years apart	
AGE Was it used to measure time or to assign people to groups?	Single Age Group	Dependent Variable Using age as a measure of how long it takes to develop		Multiple Age Groups
SOCIAL CONTEXT Who was present with the people being studied?		Significant Other Alone or With Test	Test Alone or With Experimenter	
LOCATION Where was the study done?	Unspecified	School, Home, Other, Lab, or Multiple		
BACKGROUND How many fields used as sources?			Interdisciplinary	Disciplinary Only one
APPLICATIONS Who benefited from the study?	Researchers Only			Others Professionals or individuals

Table 2. The life-cycles and dimensions of a Competing Memes Analysis for developmental research methods

Appendix B: Lotka-Volterra competition

Lotka (1925) and Volterra (1926) independently formulated competition between species in an ecosystem. The basic idea is an expansion of Verhulst's logistic law of a century earlier, which in turn built on Malthus' concept of exponential growth, where the population at a particular moment in time equals the population at the preceding moment multiplied times one plus the growth rate.

$$(1) x' = x * (1+r)$$

Populations do not grow beyond the available resources, but rather either stabilize at an equilibrium that depends on the resources or collapse after exhausting the resources. Letting k denote the equilibrium population, Verhulst corrected Malthus' notion by reducing the growth rate as the population approached the equilibrium.

$$(2) x' = x * [1 + r*(1-x/k)]$$

When the population x equals the equilibrium population k , the growth rate will be 0. The result for slow or moderate growth rates is the well known S-curve that reaches an asymptote at the equilibrium. Also, this is the equation that produces wild fluctuations with very high growth rates. Its age, simplicity and practical usefulness have made it a favorite of chaos theorists.

Lotka and Volterra further refined Verhulst's equation by reasoning that a competing species would further reduce the growth rate. They argued that the effect of each competing species would depend on its population, y , multiplied by a characteristic competitive strength factor, c . Of course, each competing species would reduce the population of the target species.

$$(3) x' = x * [1 + r*(1-x/k)] - \sum c_i y_i$$

Since, the model is commonly applied to discreet breeding cycles, it is easy to develop a spreadsheet program where the populations at a particular point of time are found in a single row and are used to calculate the populations in the successive moment in the following row. Further details of applying the model to developmental and historical data can be found in Dirlam, Gamble, and Lloyd (1999).

Acknowledgments

Most of the integrating work for this paper was accomplished in 1997-1998 while I was a James McKeen Cattell Fellow at the Laboratory of Comparative Human Cognition of the University of California San Diego. I would like to thank Michael Cole for comments on earlier versions of this manuscript and for his extensive advice and counsel over the last seven years of this project. Kurt Danziger, James Moffett, and Jerry Balzano also provided important theoretical insights on the road to refining Competing Memes Analysis. The readability and usefulness of this article was greatly improved by the careful editorial commentary of Martin De Jong. Paul Marsden also offered numerous very useful suggestions. Especially, the treatment of pioneering growth was more balanced as a result of his involvement.

USING MEMETICS TO GROW MEMETICS

1. Crises in Memetics and Psychology

As sciences, psychology predates memetics by a century. But both are facing crises. For memetics, this issue marks the end of the first incarnation of the Journal of Memetics. In psychology the United States government is reorganizing its National Institutes of Mental Health. It will now focus on helping people with mental and behavioral disorders while substantially narrowing its support for basic behavioral research in social psychology, personality, learning and memory and animal studies. The February issue of American Psychological Society Observer devoted both its feature article and its presidential column to the crisis. APS Fellow Daniel Gilbert of Harvard was quoted saying “This is an absolutely devastating blow to the infrastructure of basic science.”

The two crises are of fundamentally different sorts. The crisis in memetics stems from a dearth of empirical studies. In an age when governments, universities and foundations support empirical studies, a science without a track record has a difficult time raising funds. Established sciences, like psychology, are stronger competitors. Memetics may be a future oak tree, but currently the forest of established social sciences is using up its resources.

The crisis in psychology actually stems from a problem identified more than a half century ago by one of the greatest of early psychological scientists, Karl Lashley (1951). Psychology has no true unit of analysis for spontaneous and complex human behavior. Reflexes (including neural responses), conditioned responses, test and questionnaire responses all restrict behavioral possibilities so much that researchers are often unable to distinguish their own biases from the behaviors being studied. When compared to other sciences, these restricted-possibilities units have caused psychology to be more fraught with unresolved conflicts and less clear about scientific community directions for addressing societal problems related to its topic.

De Jong, Konstantions and Mamadouh (2002) found convincing evidence that system upheaval or severe performance crises are more fertile breeding grounds for pervasive change than other occasions. They conclude that “reformers do best when they are prepared for oncoming windows of opportunity and save their energies to act at such moments.” Though a harrowing time for the psychological research community in the United States, psychology’s crisis is a window of opportunity for memeticists to begin demonstrating how its evolutionary approach can bring practical results that people hoped psychology would address more effectively than it has.

Key to realizing the opportunity for memetics is establishing the meme as the unit of analysis for

spontaneous and complex human behavior. The view that memes are methodologically complex hampers their growth as such a unit. There are two aspects of this supposed complexity: the research triad and evolutionary data. The research triad refers to the fact that identifying memes requires three people: a model to exhibit the meme, a learner to replicate it and an experienced judge to reliably determine whether the model and learner are producing the same meme.

Replacing models with artifacts, such as videos, texts or diagrams will reduce some of the methodological complexity in the research triad. The fundamental aspect of this complexity, however, stems from the beginnings of psychology. The community trying to establish psychology as a science made an early mistake in attempting to simplify the research setting. Since then it has practiced that mistake so long, that it may as difficult to undo as to start over as a science. Danziger (1994) documented how psychology eliminated the judge from the experimental paradigm. Memetics theory, however, implies that reliable judges are not the problem. The very foundation of memetics is the fact that humanity evolved a unique capacity to reproduce the actions of other humans. The ability to judge the similarity of memes, therefore, is an evolutionarily maximized quality of humanity.

In support of the memetics implication that reliable judges are not the problem in psychological research is the fact that even the mighty computer is no competition for the human in the realm of judging the similarity of memes. The poverty of computerized speech recognition and translation compared to recognition and translation even by experienced children proves the poverty of the “eliminate-the-judge” meme for psychological research. If the computer cannot assess behavioral similarity, surely the lowly test and questionnaire are not up to the task. Memes are not methodologically over-complex; rather psychology as a science is suffering from an artificial assumption of methodological simplicity.

The second aspect of methodological complexity of the meme as unit for spontaneous, complex human behavior is its emphasis on evolutionary data. Dirlam, Gamble and Lloyd (1999) showed that developmental psychology systematically collected data on gradual changes over time only with respect to physical growth. Worse, the field gradually eliminated such studies a half century ago in favor of simplifying to one, two or a few developmental data points. Other social sciences have addressed the distribution of behaviors in space, but psychology does not even consider such distributions an issue. With such a methodological bias, it is no wonder that psychology has missed the memetic evolutionary aspects of human behavior. Again memetics is not methodologically too complex; rather, psychology is methodologically too simple.

For spontaneous and complex human behavior, the meme is a better unit of analysis than any that psychology has constructed. The problem, however, is how to grow usage of the meme in the context of overwhelming hegemony of those previously constructed units.

2. A Memetics Solution

Memetics can contribute to the growth of the meme as a unit of analysis in psychology. First, reflexes, responses, tests and questionnaires are all memes. Dirlam (2003) showed that the growth of memes obeys ecology’s Lotka-Volterra model of growth. Thus, four general factors control the growth of memes: initial strength, characteristic growth rate, resource availability and

competitive strength. In current strength, psychology's restricted-possibilities units are several orders of magnitude stronger than the meme. The problems with psychology's oversimplification of the research setting strongly suggest that the meme's characteristic growth rate and competitive strength are greater than psychology's restricted-possibilities units. This means that those interested in growing the meme must focus on the resources.

Certainly the scientific apparatus of journals, university departments, funding agencies and societies are resources. But memetics allows us to look at a more general level of the resource problem. We have a thorough conception of the general resources required by species, such as temperature, food, water etc. But at this general level, what are the resources that lead to meme growth? The psychologist, Albert Bandura (1977) devoted his career to the study of "observational learning" or imitation. In his analysis, there were four essentials: attention, retention, reproduction and motivation. This is a good starting point for identifying resources for meme growth. If the "meme-as-a-unit-of-analysis-for-psychology" meme is to spread, memeticists need to provide it with attention, retention, reproduction and motivation. Memetics history of self critique suggests that motivation is the central problem. Therefore, Bandura's criteria will be discussed in the reverse order.

2.1. Motivation

Judging from the philosophical articles on memes in both the Journal of Memetics - Evolutionary Models of Information Transmission and in collections of readings such as Aunger (2000), the central resource for growing memetics is motivation. Each of the authors had clearly attended to, retained and reproduced memetic thinking. But the question of long-term support seemed ever present. In Aunger's words "The ultimate test—which would pre-empt theoretical objections—is whether memetics can produce novel empirical work or insightful interpretations of previous results. It has not yet done so, but must do so in the near future. Otherwise, it is likely that memetics will be perceived to be a misguided enterprise. The clock is ticking." The impression is that there is a plethora of theoretical critiques and a scarcity of data. But what would motivate a change to memetic data collection both within and outside of the memetics community?

The most insightful article on motivation for change that I have encountered was the brilliant analysis of dietary change by economist/public policy analyst, Carl V. Phillips (1999). When we eat, we start with a strategy that will satisfy our needs for good nutrition, good taste, ease of obtaining and familiarity (four key resources for eating). The high fat, high sugar diet that we get at fast food chains is an example. As we practice, we get better and better at satisfying our needs with this food. In time, we get so good that when we try to change, we are usually less satisfied. From a nonlinear dynamics point of view, we have found a relative maximum. Trying to cut back within our favorite diet leaves us feeling hungry, resulting in a lower overall utility value. We easily backslide into our old habit patterns.

Eventually for some people, the strategy fails. They take a step back and consider making a radical change. They might try a vegetarian diet. This whole new strategy results in a whole new set of experiences, at first not as satisfying as the old diet. As they keep trying, they gradually get better at satisfying their four needs with the new approach. While they are working at satisfying their needs with the new approach, they frequently backslide into the old one. When they get as

good at satisfying their needs with vegetarian food as they did with fast food, however, they rarely backslide. A radical change in strategy that needs practice to get right might be called a “memeplex replacement.” Evidence presented in the next section shows that it applies not just to eating, but to all the life strategies used in complex human activities.

For memetics to succeed in psychology there needs to be a radical change in the activities of psychological researchers. To summarize the dietary analogy, people are dying from the “fast food” diet. That is motivation to try the leap to the vegan diet. Trying to maximize the four utilities without radical change will not work. It helps to have models who have shown that they can successfully maximize their utilities with the new approach, but each individual must commit to the change and then learn to make it work. To apply these concepts to psychology, maximizing the utilities of psychological research will not motivate people to change. A crisis, such as the US NIMH (the National Institutes of Mental Health) precipitated, must motivate researchers first to commit to change memeplexes and then follow up by learning how to make the new approach work.

People have died from fast food for decades. That fact has not been sufficient to create change. A rich set of data has confirmed that fast food impairs people’s health and lifestyle. A public critique of fast foods is growing. The food industry is creating new foods in response and there is a growing list of healthy food cookbooks coming from publishers. There is less data about the failings of psychology, but a public critique is beginning to emerge. Several core concepts in psychology lack hard empirical support. These include developmental stages, intelligence, the genetic transmission of psychological traits, and psychological disease. Also, if there really was a science of mind that worked, social scientists would be as much in demand in corporations and governments as biologists and engineers. Instead, at least in the U.S. policy makers seem committed to seeking biological solutions to social problems, no matter how weak the solutions may be.

Much of the early writing about memetics has involved philosophical critiques. If someone wants to help some friends change their diets, it is certainly useful to avoid suggesting a diet that would make matters worse. But the critiques of memetics have focused too much on the problems of memetics and not enough on the problems of the alternatives.

Clearly many memetics solutions are not going to be imminent, but some are. For example, the developmental stage is an almost mystical concept that at best prevents people from trying to teach concepts to children without adequate preparation. If psychologists replaced the concept of “stage” with one of memeplex change, however, it would cause educators to look for the utilities involved in the activity and to create “recipe” books that might help learners to maximize these utilities.

Likewise, psychological “disease” is a mystical concept that causes people to look for medications that alleviate the symptoms. That is roughly equivalent to solving addictions by giving drugs that block the effects of the addicted drug. A perspective that leads to some interesting possibilities for memetics is to view psychological disorders as self maintained addictions – people learning to manipulate their own neurotransmitters until their brains begin to malfunction. Such a view would motivate clinical researchers to look at the utilities of the

neurotransmitter manipulation and at how to create the commitment to change. Ultimately it might lead to developing “recipe books” for how to achieve those utilities without manipulating the neurotransmitter. As an example consider that television watching produces attentional problems (Christakis, Zimmerman, DiGiuseppe, and McCarty, 2004). In the U.S. more and more children are being given drugs for attentional problems. From a memetics point of view, a more lasting and less damaging solution would be to discover ways to serve children’s entertainment needs other than television.

Many psychologists are already struggling against the current diet of such “fluff” concepts as developmental stages and psychological diseases. They are working in areas such as naturalistic observation, qualitative data analysis, ecological psychology, observational learning, etc. The memetics community should invite such psychologists to contribute to memetics methodology.

2.2. Reproduction

From an empiricist’s point of view, empirical research in memetics is currently difficult to reproduce. No one has yet written the methodological recipe book for memetics research. A good starting point is to make analogies with ecology. Before attempting ecology’s Lotka-Volterra model, I spent a frustrating decade looking for a mathematical model that fit data from over 1,200 drawings made by 5 to 18 year olds and coded for nearly 30 drawing qualities by three independent judges. Probability theory offered a reasonably good fit using the generalized gamma law developed in the context of radioactive decay from one element to another. But why development would proceed by decay was a mystery. The ecology equation, however, fit the data like a statistical skin-tight glove. When the same equation fit data on the historical development of developmental research methodologies (as coded by two independent judges in nearly 1000 journal articles written from 1930 to 1992), it opened up several powerful theoretical insights:

- A competing-agent action of the qualities in both settings fits well with the meme concept.
- An outside-of-the individual status of the qualities also fits the meme concept.
- Decay happens because later memes compete with earlier ones.
- “Development” refers to changes in the frequency of use of competing memes described above as memeplex replacement.
- An easy to study developmental succession of memeplexes replaces the fluffy stage concept.
- The easily researched process of commitment to radical change followed by relearning readily replaces the inferred process of developmental stage acquisition.
- Controlling factors of meme populations are initial frequency, growth rate, resources and competitive strength.

Given constant resources, four growth patterns identify four categories of memes:

- Default – high initial strength, low growth rate and competitive strength.
- Pioneering – high growth rate (enough to exhaust all resources in the absence of competition), low initial and competitive strengths.
- Niche – high competitive strength, low initial strength and growth rate.
- Dominant – high competitive strength, low initial strength, moderate growth rate ((not enough to exhaust all resources in the absence of competition).

Other analogies from ecology should produce similarly powerful insights not only for human development but for memetics research related to all the social sciences.

2.3. Retention

Key factors that influence retention are repetition, organization, context similarity and distinctiveness. Repetition, organization and context similarity factors depend on growth. Based on Google searches “Memetics” currently appears on the internet about 0.1% as often as the term “internet” itself (controlling for growth in the internet as a whole), as often as “psychotherapeutic”, 3% as often as anthropology or sociology and 1% of psychology. It’s ranking among such terms grew rapidly last fall, but has declined this spring. The crisis represented by the journal change may be a key reason for the recent decline. Since there are none of the other traditional academic resources mentioned above for memetics, a large impact of a change in the only journal might be expected. In this context, closing the journal would be roughly akin to people aspiring to change from a fast-food to a vegan diet by throwing out their only vegan recipe book.

The remaining factor is distinctiveness. There have been numerous distinctive contributions to memetics. Topics ranging from anti-religion and anti-self to paganism and marketing are reminiscent of the early days of psychology amplified by a century-and-a-half of self preoccupation. Few of these distinctive contributions, however, have an empirical basis. The deeper question is whether there is a distinctive memetics methodology.

Two candidate methods that set memetics apart from the other social sciences have already been mentioned. The first is the model-learner-judge triad and the other is measurement of the frequency distribution of memes in time and space. Again a comparison of ecology and psychology is illustrative. I counted the frequency of tables and charts in a standard textbook of ecology and one of psychology. From beginning to end of the ecology textbook, about 75% of the charts and tables involved distributions in time or space. The same was true for the first portion of the psychology text that dealt with sensation, perception and conditioning. The last portion of the psychology text, however, dealt with personality and social psychology. For that portion, the ratio was reversed—only 25% of the tables and graphs involved distributions in time or space. Because psychology views the mind as being inside the brains of individuals, it does

not consider mapping the distribution of complex human behaviors in time and space. Because memetics views the human mind as dependent on relationships with other humans, past and present, distributional data is central to memetics methodology. Distributional data made the theory of evolution both possible and established. It will also yield the distinctive findings needed to establish memetics.

2.4. Attention

Memetics needs empirical studies. Empiricists pay attention to empirical results. Those that attract the most attention solve intractable societal problems. If memetics is to help solve such problems it will be through its emphasis on adaptive growth. Growing a reduction in crime within a city, a more equitable way to distribute food in an underdeveloped country, a reliable reduction in dependency on addictive drugs or self-manipulated neurotransmitter changes in individuals, or an improvement of skill in a school population would all be spectacular results that would certainly attract attention. If memetics researchers tackled the worst problems in their environment by collecting evolutionary data using the model-learner-judge triad, the results would establish memetics as a science.

3. Conclusions

There is a window of opportunity for memetics resulting from the current crisis in U. S. funding for psychology. To realize the potential of this window memetics must provide other social sciences with the four essential resources for imitation: motivation, reproduction, retention and attention. The discussion showed that the following four strategies will grow the use of memes in the social sciences:

(1) Motivate social sciences by critiquing current paradigms, by calling for a commitment to a radical shift of units of analysis to those involving experienced human judges and the collection of evolutionary data and by encouraging methodological articles in memetics by those already using such units.

(2) Help researchers reproduce memetics by providing methodological models which borrow heavily from analogs of approaches found to be successful in ecological and evolutionary research.

(3) Help researchers retain the memetics approach by repeatedly emphasizing the model-learner-judge triad and the charting of changes in frequency across time and space.

(4) Attract researcher's attention to memetics by tackling spectacular problems.

Abstract

It appears that what the agents in a multiple agent system believe is typically partial, often wrong and often inconsistent, but that this may not be damaging to the system as a whole. Beliefs which are demonstrably wrong I call *misbeliefs*. Experiments are reported which have been designed to investigate the phenomenon of collective misbelief in artificial societies, and it is suggested that their results help us to understand important human social phenomena, notably ideologies.

Keywords: Multiagent system, collective belief, ideology

Introduction

1.1

Using computers to simulate naturally occurring societies is a rapidly growing area of research (Gilbert and Doran, 1994; Gilbert and Conte, 1995). Much of the ongoing work is set at the level of societies in which each individual is relatively low on the cognitive scale, but some aims to gain insight into human society, addressing such issues as social action, cognized models, group formation, planned cooperation and "macro-level emergence". The techniques of distributed AI (O'Hare and Jennings, 1996) may be used to support this latter work.

1.2

Some explanation and justification of methodology is appropriate. By working in the computational domain we are able to study multiple agent systems *independently* of any particular modeling interpretation. We can establish rigorously and objectively what consequences, including non-obvious consequences, flow from what assumptions. We can therefore hope to develop an abstract theory of multiple agent systems and then to transfer its insights to human social systems, *without an a priori* commitment to existing particular social theory. Of course, at a certain level assumptions must be built into whatever systems we create and experiment with, but the assumptions may be relatively low level, and their consequences (including emergent properties) may be discovered, not guessed.

Agents and Artificial Societies

2.1

Agents may be characterized as computational mechanisms situated in an environment that repeatedly select and perform actions in the light of their current input from the environment (perception) and their current internal state. In general, the actions that agents may perform include the sending of messages to other agents.

2.2

A variety of different agent "architectures" have been designed in recent years and their properties partially explored (see, for example, Wooldridge and Jennings, 1995; Wooldridge, Muller, Tambe, 1996). One simple type of agent architecture, often called a *reflex agent* (Russell and Norvig, 1995), comprises the following main components:

- A *working memory* (comprising a changing set of tokens, determined by processes of "perception")
- A set of *rules* of the form IF <CONDITION> THEN <ACTION>. Such rules are often called "situation-action" rules or "condition-action" rules. The condition part of the rule typically specifies a required conjunction of tokens in the working memory (the specification may involve variables which must be bound to tokens in a consistent way) and the action part an executable procedure.
- A process that repeatedly identifies a rule whose condition part matches the contents of the working memory, and then executes that rule's action procedure -- thereby causing the agent to perform one or more actions in its environment.

Thus the essential functioning of the agent is that the results of perception are deposited as tokens in the working memory, and matching rules are "fired" -- with the result that actions are performed by the agent in its environment. The heart of such an agent is thus the set of condition-action rules which it contains.

2.3

A standard extension to this design is to add a semi-permanent body of (symbolically coded) information to the working memory, an *agent memory*, and to include rules which update the contents of both the working memory and, from time to time, the agent memory. The agent is then, in effect, able to maintain and update some sort of representation of and beliefs about its environment. This type of agent, which may be called an *extended-agent*, will be that at issue for the remainder of this paper.

2.4

A computational multiple agent system is then a set of agents (here extended-agents) which share an environment and which interact and possibly pass messages in some form one to another. The agents in a computational multiple agent system are sometimes referred to as an *artificial society* (Gilbert and Conte, 1995; Epstein and Axtell, 1996).

Beliefs and Collective Beliefs

3.1

I take a simple but sufficient view of what it means for an extended-agent to *believe p*. This is that *p* may be "decoded" from the agent's memory -- which implies that there are systematic processes by which suitably coded propositions are added to and deleted from and manipulated in the agent's memory and which, as viewed by an outside observer, are consistent with the working of its perceptual and effector processes. I also limit consideration to beliefs which are essentially descriptive, and ignore the matter of degrees of belief. For a much more developed notion of belief see Mack (1994).

3.2

By a *collective belief p* of a group of agents, I mean merely that the great majority of agents in the group in question have the belief *p*. This definition is about the simplest possible. There is no requirement, for example, for agents to believe that others hold the belief *p*, still less any notion of mutual belief or belief associated with a role. The collective beliefs (or *collective belief system*) of a group of agents are then those beliefs that occur widely amongst the agents. Again, this simple concept of collective belief, imprecise though it is, is sufficient for our purposes. For more developed theories of group belief see Tuomela (1992) and Wooldridge and Jennings (1998).

The Impact of Belief upon Behaviour

3.3

An extended-agent's behaviour is determined by a combination of its beliefs and its rules. At first sight, it may seem somewhat counter-intuitive that to change an agent's behaviour one may change either its rules *or* its beliefs, but this is clearly so. If the beliefs in an extended-agent's memory are changed then, assuming a fixed rule set, the actions it performs will change. In human terms, I will behave differently when I awake in the morning if I believe it is Sunday rather than Monday. More dramatically you can perhaps make me "commit suicide" if you can make me believe that a glass of nitric acid is a glass of water -- or that the dead go to a "better world".

Misbelief

3.4

The examples of the foregoing section raise the issue of the accuracy of beliefs. When an agent believes something which is (from the point of view of an external observer or experimenter) demonstrably NOT the case in its environment, I speak of the agent's *misbelief*. There is an analogous notion of *collective misbelief*. Of course, an agent may have beliefs whose soundness is difficult to determine. An agent may, for example, believe that there are two types of agent in its world, those that should be attacked if possible and those that should not. How does one assess the soundness of such a belief?

3.5

In general, sources of limited or mistaken belief in a multiple agent system may easily be identified. They include:

- Limited and faulty perception. An agent may be unable to perceive what is the case (e.g. because it is too far away) or may misperceive.
- Limited and faulty communication. One agent may fail to pass information to another, or may do so in such a way that errors are introduced.
- Beliefs becoming inaccurate with the passage of time. An agent may persist in a belief long after it has ceased to be accurate.
- Faulty generalization.

3.6

To the extent that these factors are at work within the agent community partial, inconsistent and errorful belief may occur and may well be the norm. Further, to the extent that there is *belief harmonization* between spatially neighboring agents, for example by agents communicating possibly erroneous beliefs one to another ("Have you heard, the Martians have landed?"), collective misbelief will also be the norm. Belief harmonization may be achieved in many ways. All that is required is some process which tends to bring the beliefs that neighbouring agents hold into agreement, irrespective of their soundness.

3.7

It is natural to suppose that collective misbelief must be detrimental to the society of agents in question. However, it is easy to see that this is not always the case. To take a human example, consider a group who (incorrectly) believe that a certain stream is holy so that water may not be taken from it. This may be to their detriment. But it may also be to their benefit if the stream is dangerously contaminated in some non-obvious way. Indeed it has been argued that collective misbelief may often be *necessary* for the survival of those who hold it. Thus the anthropologist

Roy Rappaport, discussing the importance of the Tsembaga people's *cognized model* (which loosely corresponds to what is here called "collective belief") remarks: "It can thus be argued that the cognized model is not only not likely to conform in all respects to the real world... but that it must not" (Rappaport, 1984, page 239). He is referring particularly, but not exclusively, to the way in which socially beneficial ritual truces between different sections of the population are reinforced by mutual fear of the anger of their (dead) ancestors should a truce be violated.

Experimental Scenarios

4.1

Now I discuss experimental work intended to explore the genesis and impact of collective (mis)belief. A typical experiment involves the "evolution" of (the beliefs of) a population of agents in a specified environment, so that the emergent properties of the population may be related to its initial properties and to the properties of the environment. The evolutionary process itself is akin to the techniques of genetic algorithms and genetic programming, and the emphasis on the evolution of beliefs is similar to Dawkins' (1989) notion of evolving populations of self-propagating ideas or *memes* (to which I shall return later).

4.2

In Doran (1994) I reported the properties of an artificial society set "on a line" which was simple enough to be given a full mathematical description, and whose simulation properties demonstrated the potential impact of a certain type of collective misbelief which may be called *attribute error*. Attribute error is present where agents do not hold false beliefs about the existence of entities in their world, or the types of those entities, but are in error about their more detailed properties -- such attributes as colour or dimension. In the experiments reported it was shown, in brief, that in certain circumstances the population of agents would typically evolve to a steady state in which their collective beliefs about their own precise locations on the line were inaccurate, but had the effect of enhancing individual agent survival and hence increasing average population size. Here I report experiments with more complex computational systems which are no longer capable of simple mathematical description, but which nevertheless enable the investigation into collective misbelief to be taken further.

The Scenario-3 Testbed

4.3

The experiments to be described used the software testbed SCENARIO-3 (written in the programming language C) which supports in simulation:

- a two dimensional spatial environment
- mobile agents and immobile resources
- (limited) agent perception of their surroundings
- agent internal representations of other agents and of resources (including memory limitation and forgetting)

- agents moving towards and harvesting resources for energy (in mutual competition)
- agent death by starvation or by aging
- (asexual) reproduction
- one agent killing another

The passing of time is simulated within the testbed as a sequence of "time units", within each of which events at different locations (e.g. the movements of agents) take place simultaneously.

4.4

Words such as "harvesting" and "killing", used to aid intuitive understanding, denote relatively simple events within the testbed. For example, "harvesting" is said to occur when an agent located at a resource reduces the energy level of the resource to zero, and increments its own internal energy store by a corresponding amount. Energy is used up by an agent (reducing its energy store) as an agent moves around in the testbed. "Killing" involves two agents meeting and one possibly becoming "dead" (and deleted from the world) and the killer acquiring the killee's energy store. One agent maintains a representation of another when it holds information (not necessarily accurate) about the other and about some of the other's characteristics.

4.5

In the SCENARIO-3 testbed, many important parameters are under the control of the experimenter. These include the perceptual range of the agents, their rate of movement, the range over which agents can communicate one with another, and their memory capacity. And many potentially complex sequences of sub-events, for example those which in principle would determine each particular agent reproduction, are bypassed by an appeal to suitably chosen probability distributions.

Experiments I: The Impact of Pseudo-Agents

4.6

The set of experiments I shall now describe focuses on awareness by agents of other agents and of self-renewing energy resources, and on action to harvest them. It particularly concerns the impact of agents (mis)believing in non-existent agents -- what may be called *existence errors* (in contrast to the *attribute errors* of the work briefly outlined earlier). The experimental scenario includes simple forms of agent death and reproduction.

The First Experimental Scenario in Detail

4.7

N agents and M resources are located on a plane. They are initially randomly distributed in the unit square with corner points (0,0), (0,1), (1,1), (1,0) in rectangular coordinates, but agents may leave this square as the experiment proceeds. Resources have fixed locations. Each agent has an energy level, which declines with time and which is restored by resource consumption.

Resources renew periodically, which implies that there is a maximum carrying capacity for the environment

4.8

If an agent's energy level declines to zero, the agent dies and is removed. Further, if an agent enters a particular "fatal" zone (the circle centered at [0.5,0.5] and with radius 0.25) it immediately dies. In each time unit, there is a small probability that any given agent may reproduce, that is, create an exact copy of itself located at an adjacent point).

4.9

The actions taken by an agent in each time unit, in order, are the following:

- Harvesting and consumption of immediately adjacent resources
- A small random movement
- Movement towards the nearest resource *to which it believes itself the nearest agent*. This movement will only occur *if there exists such a resource*. The underlying idea is that there is no point in an agent trying to harvest a resource when some other agent is better placed to harvest it.

4.10

In these experiments, agents are aware of the current locations of all resources and agents in the environment. Additionally, they may (mis)believe in the existence (essentially, the location) of a small number of agents that do *not*, in fact, exist in the environment. I refer to these as *pseudo-agents*. Pseudo-agents do not move and cannot, of course, consume resources. It follows that an agent may pass up a good opportunity to harvest a resource from belief in a pseudo-agent.

4.11

Initially, each agent independently (mis)believes in a small set of randomly generated pseudo-agents. Different agents believe in different pseudo-agents. Such beliefs are typically handed on from 'parent' to 'child', with a possibility of random variation when agents' energy levels are low. In addition, and importantly, the testbed may be set so that agents tend to harmonize their beliefs with their nearest spatial neighbours. Specifically, agents are scanned in turn in each time unit, and each takes over the beliefs (about the locations of pseudo-agents) of its nearest neighbour where they differ from its own. If the circumstances are right, therefore, a particular pattern of (mis)beliefs may spread through the population.

4.12

Each agent decides its movements by reference to all its current beliefs, including beliefs about pseudo-agents, not by reference merely to the actual state of the environment. The agents in no way distinguish between real and pseudo-agents when deciding their actions.

Results and Discussion

4.13

In systematic experiments it has been found that the agent society enters semi-stable states in which agent survivability is demonstrably enhanced by collective misbelief in small sets of pseudo-agents. Typically, most of the agents in the society come to share (mis)beliefs in a small number of pseudo-agents in the fatal zone. This causes these agents to seek resources elsewhere, away from the fatal zone and therefore more safely. The effect is to maintain a substantially (about 50%) greater agent population than would otherwise be the case (as determined in control trials). In evolutionary terms, what happens is that groups of agents with particular collective beliefs "compete", and those groups with beliefs which help them to survive tend to increase their numbers at the expense of the remainder.

4.14

Simple though these experiments are, they do illustrate the socially beneficial impact of what is perhaps the most straightforward type of misbelief that can occur in a multi-agent system -- existence errors.

Experiments II: "Cults"

4.15

The second set of experiments involves a significantly different type of misbelief, *category error*, where an agent assigns an entity to the wrong type category and reacts to it accordingly. Thus in this particular experimental scenario, agents can come to believe that a non-agent, that does indeed exist, is an agent. There is also a more complex interaction between misbelief and behaviour.

4.16

These experiments again use the SCENARIO-3 testbed, but now using that feature of the testbed which enables agents, in certain circumstances, to "kill" one another. Also new are a particular type of agreement, a *friendship* and, crucially, the notion of a *resource agent*.

Friendship

4.17

An agent may decide that another agent, which it happens to meet, is its *friend*. The chance of such an outcome to a meeting is determined by the experimenter. If an agent *X* does come to "think of" an agent *Y* as a friend, then *X passes information about resources to Y (e.g. their locations) whenever Y is within message passing range AND X never attempts to kill Y*. Note that friendship is not necessarily symmetric. *X* may treat *Y* as a friend whilst *Y* does *not* so treat *X*.

4.18

There is another important aspect of friendship. *An agent X will not attempt to kill an agent Y (even though X does not view Y as a friend) if it is the case that X and Y have a believed friend, say agent Z, in common.* This latter aspect of friendship is crucial to what follows.

Resource Agents and Cults

4.19

The testbed may be set so that from time to time an agent "agentifies" a resource, that is, wrongly comes to think of a resource as if it were an agent. We may call a pseudo-agent like this a *resource agent*. In its thinking an agent does not distinguish between resource agents and real agents, so an agent may even regard a resource agent as a friend and act towards it accordingly. Of course, messages sent to a resource agent go nowhere.

4.20

Once an agent forms a representation of a resource agent, that representation may be passed to other agents by inter-agent communication. It may also be passed from one agent to its offspring. If the circumstances are right, therefore, the representation may spread. When a set of agents all come to believe in the same resource agent, and that they have that resource agent as a friend, we may call that a *cult*. The resource agent in question may be called the cult *head*. It follows immediately from the properties of the friendship relation given earlier that the members of a cult will not kill one another.

Results and Discussion

4.21

What is found experimentally is that even a very low-frequency possibility of agents coming to believe in resource agents can regularly lead to the formation of large and enduring cults and that, all other things being equal, killing in the society is then greatly reduced and the average population of the society over time increased.

4.22

To give the reader a feel for these experimental trials and what happens within them, there follows a summary account of key events in one typical trial (and see Figure 1). The agent and resource identifiers are exactly as they appear in the testbed and its output:

Resource number 11 was initially 'conceived' as a friendly agent, 110000000rrr, by agent number 248 in time unit 251.

At time 268 this resource agent had just one 'host' agent in a population of only 3 agents - not agent 248, which died before time 268, but agent 8000254. A cult around 110000000rrr built up

thereafter (comprising descendants of 8000254), typically containing about 30 member agents, and lasted for hundreds of time units.

Initially the cult was also around a 'dead' real agent 20000267 which itself had lived for only one time unit, but was also regarded as a friend by agent 8000254. However, memory of 20000267 was lost in time unit 287.

4.23

Note the appearance of a "dead" agent in the account. The potential of dead agents as cult heads was not anticipated, though obvious enough in hindsight. In fact, a dead agent is not as effective as a resource agent as a cult head because the latter, unlike the former, can be "seen" and awareness of it thereby refreshed. What matter most for the formation and indefinite survival of the cult is the effective "immortality" of its head.

4.24

It should be made clear that these experimentally observed phenomena are not entirely straightforward to obtain. As was indicated earlier, the agent society and world embody many parameters (e.g. dimensions, the rate of renewal of resources, agent perception range, agent rate of movement, agent life span, agent memory span, the probability of a new friendship in any time unit, the probability of an agent seeing a resource as a resource agent in any time unit), and different combinations of settings for these parameters often lead to very different outcomes. A heuristic is that the chance of cults is greater the greater the contrast between the "immortality" of the potential cult head and the "mortality" of the potential cult members. Thus relatively short agent life and memory spans make the formation of cults more likely.

4.25

Current experiments are focussing on the dynamics of multiple competing cults each exploiting several resources, and with each agent possibly a member of several cults. These experiments raise such issues as competition between cults, and also the formation of hierarchies topped by a cult head.

Future Work

4.26

The two sets of experiments reported have demonstrated that it is possible to evolve collective misbelief systems in an artificial society which interact in such a way with prior rules governing agent behaviour that the society as a whole benefits. Some of the relevant conditions have been established. But much more experimental work needs to be done to approach a full understanding. Thus the connection between different patterns of misbelief and their impact upon different types of environment needs further examination. Is it the case that in more realistic scenarios the possible benefits of collective misbelief tend to be outweighed by disadvantages?

4.27

For any particular collective belief system, two different questions may be asked: how effective is it in context? And how may it come into existence? These two questions are not as well separated as they should be in the experiments reported here. And the answer to the latter question is surely more than the *ad hoc* random processes incorporated in Scenario-3 (see next section).

4.28

Finally, what may be called *biased* belief systems merit investigation. These are belief systems whose effect is to favour one subset of the agents in the system against another. It might be, for example, that agents with certain characteristics are rewarded by the belief system in a way that would not be so were another belief system in place.

A Computational Theory of Ideologies?

5.1

The foregoing experiments and associated discussion related to agents in computer based artificial societies. But any discussion of collective belief and misbelief in a system of non-trivial agents, and its functional significance, prompts consideration of a connection with the "social construction of reality" and with "ideologies" in the sense that they are studied in social science. By "ideologies" social scientists typically mean systems of belief held in a society which enable and validate action (especially group motivated action) and/or erroneous belief systems which enable or support domination of one human group or class by another (e.g. Thompson, 1984). It seems reasonable that insofar as ideologies may be regarded as observable features of human society and may be objectively studied (which is admittedly a matter of some controversy), then studies of collective belief and misbelief in DAI agent systems must be one way to further our understanding of their dynamics.

5.2

Approaching ideologies from an AI and artificial societies standpoint, with a consequent emphasis on the connection between micro and macro social phenomena, makes it natural to suggest that the origins of ideological beliefs lie in the inherent cognitive ability of individuals to manipulate beliefs, by adaptation, generalisation or processes of "generate and test", in a manner which is heuristic rather than fully reliable. Manipulation of kin beliefs and concepts may be especially significant (compare Read, 1995), a possibility explored in the context of the EOS project by Mayers (1995). It also seems likely that a significant impact of ideologies is to coordinate the actions of people and to limit, in effect, their individual autonomy by creating "social norms" so enhancing survival. This is the view argued by Rappaport, 1971. Conte and Castelfranchi, 1995, and Ephrati et al., 1995, have recently reported computer based studies from a similar standpoint.

5.3

In all this work there is a close relationship with *memes* (Dawkins, 1989), that is, ideas or beliefs which propagate and evolve in the *noosphere*, the collective mental space of a population. Computer based experimental work by Bura (1994) and Hales (1997) has studied in detail the dynamics and functional impact of memes and meta-memes in simple artificial worlds. Further, the work reported here should also be compared with that of Reynolds (1995). The collective beliefs studied by Reynolds, however, are differently represented, and are primarily directed to effective problem solving.

Conclusions

6.1

It is clear that belief and collective misbelief are inevitably at the heart of the behaviour of natural and artificial societies. Further, collective misbelief is not necessarily something to be avoided -- it may be functional if matched to the agents' environment. This observation is not in itself new. What is new and demonstrated here is our emerging ability to address particular questions and conjectures about such issues by way of precise and targeted computer-based experiments in which functional collective misbelief (involving attribute, existence and category errors) is evolved in an agent society. This has important implications for the study of ideologies in human societies.

THE REVEALED POVERTY OF THE GENE-MEME ANALOGY: WHY MEMETICS PER SE HAS FAILED TO PRODUCE SUBSTANTIVE RESULTS

By

Bruce Edmonds

Centre for Policy Modeling

Manchester Metropolitan University

Over two years ago in this journal I challenged the memetics community to meet three challenges (Edmonds 2002). My prediction was that if these were not substantially met that memetics as a distinct approach would not survive. Despite some attempts to do this these challenges were not met, at least not within the terms I had proposed. Now JoM-*EMIT* in its current form has ceased due to a lack of quality submissions. Whilst I do not claim that the former caused the later, I do claim that the failure to answer those challenges was indicative of the poverty of the memetics project resulting in a lack of demonstrable progress which, in turn, has meant that it has failed to interest other academics.

Here I distinguish between what might be called the "broad" and the "narrow" approaches to memetics. The former, broad, approach involves modeling communication or other social phenomena using approaches which are evolutionary in structure. Work within this approach is often done without appealing to "memes" or "memetics" since it can be easily accommodated within other frameworks. In other words, it does not require an analogy with genetics. The later, narrow, sense involves a closer analogy between genes and memes – not necessarily 100% direct, but sufficiently direct so as to justify the epithet of "memetics". What has failed is the narrow approach – that of memetics. Work continues within the broad approach, albeit under other names, and in other journals.

I claim that the underlying reason memetics has failed is that it has not provided any extra explanatory or predictive power beyond that available without the gene-meme analogy. Thus whilst the idea of memes has retained its attractiveness for some in terms of a framework for thinking about phenomena, it has not provided any "added value" in terms of providing new understanding of phenomena. The fact that some who wear the theoretical spectacles (Kuhn 1969) of memetics insist of redescribing a host of phenomena in these terms despite the lack of substantive results merely confirms other academics' opinion of the approach. The ability to think of some phenomena in a particular way (or describe it using a certain framework), does not mean that the phenomena has those properties in any significant sense.

Academics who seek to study memetics in serious ways have suffered in the respect that they are often confused with those on the penumbra for whom memetics is a fad. However, this mistake is grounded in an element of truth. The study of memetics has been characterized by theoretical discussion of extreme abstraction and over ambition. Thus for example, before any evidence is available or detailed causal models constructed, attempts have been made to "explain" some immensely complex phenomena such as religion in general [note 1] or consciousness. This sort of discussion shifts any study of memetics from the realm of science to that of a philosophy and,

on the whole, this philosophy has adopted the subsumption tactic (Hull 2001), seeking to generalize explanation rather than been productive of essentially new insights.

In the broader sense it would be extremely surprising if there were no social processes with evolutionary aspects. However, the intricacy of social phenomena means that understanding the effects of different mechanisms in systems of multiply interacting actors requires a finer tool than that of discursive analogy. Thus unraveling some of the conditions for observed social processes (which may have evolutionary aspects) requires such tools as agent-based computational simulation which can track long-chains of intricate interactions. This approach also allows for a wide variety of different mechanisms and processes to be explored and not merely those amenable to description via biologically-rooted analogies. Of course, there is a successful community of social simulators who study, among other things, evolutionary models of information transmission [note 2]. Similarly there is work in computer science, applying evolutionary ideas to computational processes and work in theoretical biology studying non-genetic evolutionary processes. Thus this wider work will continue as subsets of other projects, but not under the discredited label of memetics.

To illustrate how the memetics bandwagon may have peaked I used ISI's large citation index (<http://www.isi.org>) and Google Scholar (<http://scholar.google.com>) to estimate the number of papers that mention the word memetics. I picked "memetics" rather than "meme" (which has a longer history) because of the existence of the common French word "meme" (as in le meme chose). I subtracted those papers about "memetic algorithms" because these are not about memes in any meaningful way [note 3].

Figure 1. Number of papers mentioning "memetic*" (but not "memetic algorithm*") each year according to Google Scholar (numGS, pink circles) and on the ISI's citation index (numWOS, blue circles). Lines are 6th degree fitted polynomial trend lines of the respected series

The fact is that the closer work has been to the core of memetics, the less successful it has been. The central core, the meme-gene analogy, has not been a wellspring of models and studies which have provided "explanatory leverage" upon observed phenomena. Rather, it has been a short-lived fad whose effect has been to obscure more than it has been to enlighten. I am afraid that memetics, as an identifiable discipline, will not be widely missed.

Notes

Here I want to distinguish woolly explanations of religion in general from the more careful study of the phylogeny of particular institutions such as in (Lord and Price 2001).

The success of the Journal of Artificial Societies and Social Simulation (<http://jasss.soc.surrey.ac.uk>) contrasts markedly with that of JoM-EMIT.

"Memetic Algorithms" are Genetic algorithms but where hill-climbing is used to locally optimize solutions. No spread of solutions is involved (unlike a few other evolutionary computation approaches which I have included).

THE EVOLUTION OF LANGUAGE AND SCIENCE STUDIED BY MEANS OF BIOLOGICAL CONCEPTS

By

Börje Ekstig

Department of Teacher Training
Uppsala University, Uppsala Sweden
borje.ekstig@ilu.uu.se

Abstract

This study examines certain mechanisms underlying the evolution of language and science — including mathematics — using concepts developed in the field of biological evolution. Developmental processes are particularly emphasized. Analysis of developmental processes, such as human embryonic development, children’s verbal development, and adolescents’ scientific conceptual development reveals the unifying principle referred to as “condensation” — the successive shortening of developmental stages. The mechanism of condensation is coupled to the rate of evolutionary change.

The analysis examines the applicability of the concept of the meme. Regarding the evolution of language, we suggest a cooperative combination of genetic and memetic replication; while early on in the evolution of science only memetic replication is envisaged.

Key words: Evolution, development, memes, cultural evolution, language, science, mathematics.

1. Introduction

This paper examines the mechanisms underlying the evolution of language and science, applying concepts developed in the field of biological evolution. Common to these various manifestations of evolutionary process is developmental growth, as observed in the embryo, child, and adolescent. The significance of the developmental process in its various guises forms the main subject of my study. Such a broad approach is highly multi-disciplinary, and in this introduction I will comment on some relevant fields of research.

In an early work, Stephen J. Gould (1977) reviews the widespread notion of a coupling between the developmental and evolutionary processes. More recently, our rapidly growing insight into genetics has lent this controversial field renewed respect. One such new field of research focuses on the developmental genetic machinery that underlies embryological phenotypes (Arthur 2002). It is recognized that evolutionary change occurs not by direct transformation of adult ancestors into adult descendents, but rather when developmental processes produce the features of each generation in an evolving lineage (Raff 2000). Wagner et al. (2000) have examined another theme, the role of development in the origin of evolutionary innovations. In this study I will build on the same principal insight of the central role of development, but restrict my discussion to the lineage of humans.

Concerning cultural evolution, there is an overwhelmingly abundant literature on the relationship between cultural and biological evolution within which one can discern several different approaches. One such approach is socio-biology. As Edward O. Wilson has suggested, certain cultural norms may survive and reproduce better than other competing norms, causing culture to evolve along a track parallel to and usually much faster than genetic evolution. Wilson, however, contends that the connection between genes and culture is never completely broken and discusses this connection in terms of gene-culture co-evolution (Lumsden and Wilson 1981), a concept that supports the general notion of a close relationship between cultural and biological evolution.

Another approach that examines the connection between cultural and biological evolution is memetics—an approach likely familiar to readers of this journal. Memeticists attempt to explain cultural evolution without reference to any benefit for genes. The Darwinian principle of natural selection is expanded, and is regarded as working not only on genes but also on memes. Works by Dawkins (1976), Dennett (1995), and Blackmore (1999, 2000) introduce and develop the concept of memes. These authors attempt to grant memes an analogous role in cultural evolution to that played by genes in organic evolution. I will analyze this idea at length in this investigation.

In studying children's psychological development, psychologists have attempted to apply concepts from evolutionary theory. Advocates of this influential field of research, called evolutionary psychology, emphasize that understanding the principles governing evolution is indispensable in attempting to understand human nature (Tooby and Cosmides 1992, p. 50). Such a general statement may stand as a guiding principle for the present investigation. However, if I have understood evolutionary psychologists correctly, they also seem to imply that all behavior ultimately comes back to genetic advantage. Such a view is questioned, for instance by Dennett and Blackmore, and I will demonstrate that genes are insufficient to explain many characteristics of cultural evolution.

Language is an important constituent of culture, and there is a tremendously rich literature dealing with the enigmatic question of the origin and evolution of language. There has recently been exciting debate as to whether or not language has evolved by means of a principle analogous to natural selection; Dennett provides a survey of this debate (1995, pp. 384-400). I suggest that any explication of the evolution of language, while incorporating elements from natural selection, should have recourse to additional mechanisms as well.

There is a widespread notion that the evolution of science has much in common with biological evolution. Thus Blute (2003), for instance, discusses a new field of research called evolutionary ecology. I will refer to such analogies, and in particular analyze their implications for children's and adolescents' learning of science.

The referenced literature testifies to the many notions of connections between cultural and biological evolution. These connections are elaborated in the analysis I will propose in this paper. It builds on my previously introduced model (Ekstig 1985, 1994), and here I will focus on the evolution of language and science. First I will recapitulate the main features of the model.

2. The pattern

My study assigns the developmental processes of individual human beings a central role in the analysis of biological and cultural evolution. The role of development in biological evolution stems from the fact that genes carry and transmit instructions for self-replication and for development, not for evolution, and because organic evolution proceeds as a result of continuous modifications in the developmental program. The continuity of this process means that many vestiges of early evolutionary stages are stored in the genes and manifested as phenotypic developmental stages in the present-day embryo. Or, as Darwin long since observed, “the embryo comes to be left as a sort of picture, preserved by nature, of the former and less modified condition of the species” (1859, p. 338). Such common stages or traits, called parallels, are thoroughly examined by Gould (1977).

Likewise, the continuity of the transmission of cultural traits over generations means that stages from our cultural history are now discernible as developmental stages in the present-day child and adolescent. Such parallels in the cultural realm have long been observed and discussed, and are also surveyed in Gould’s review. In the field of mathematics and physics, Piaget and Garcia (1983) have reported a thorough study in which they find striking coincidences.

I have earlier (1994) analyzed the relationship between individual development and the evolutionary process, taking as a point of departure the pattern that appears when the developmental age at which each trait appears is compared to the period of time that has elapsed since it first arrived on the scene in evolutionary history. The essential features of the model appear in Figure 1. The pattern encompasses both the organic and mental aspects of human development, and indicates an intimate relationship between biological and cultural evolution.

As is immediately obvious, the diagram includes very few of the traits found in a growing organism. The principle behind the selection of the traits forming the pattern, organic as well as cultural, is that these traits appear in an inflexible order in the individual’s developmental program as well as in the evolutionary process. I suggest that such traits be denoted cumulative traits.

Organic evolution proceeds through the successive addition of novel developmental traits, thus forming the evolutionary pathway of the species. These novel traits predominantly manifest themselves towards the end of individual development, i.e., just before sexual maturity, because, by and large, the progeny’s genetic constitution is not influenced by selection exerted on the parent after conception. These novel traits are called terminal additions, and since they manifest themselves before sexual maturation they tend to lengthen the development process and therefore also generation length. However, there is a counteracting process as well.

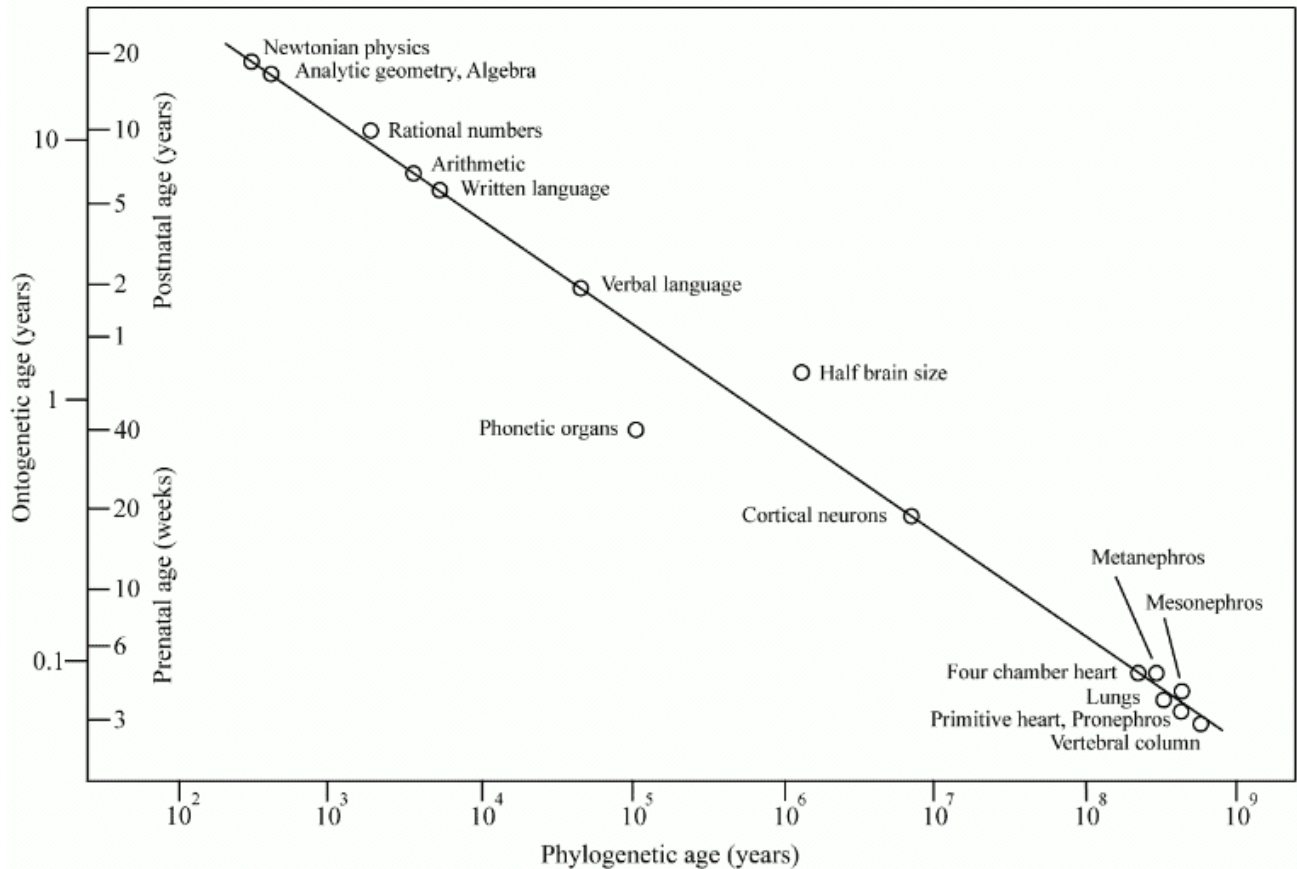

Figure 1. Diagram of ontogeny versus phylogeny in the lineage of humans
The ontogenetic age is measured from the moment of fertilization. The ordinate also gives the individual's postnatal and fetal ages. Both scales are logarithmic. The diagram is a revised version of a diagram appearing in Ekstig (1985), and the reader is referred to that reference for comments. It should be mentioned that the uncertainty regarding the Phonetic organs point is very great. If the phylogenetic age is assumed to be one million years, which is not unrealistic, the point will be situated on the line.

3. Condensation

Lineages with shorter generation lengths increase their relative number in the gene pool. Hence there is a ubiquitous selection pressure favoring shorter generations, as analyzed in life-history theory. Stearns (1992) shows that for organisms that mature earlier, generation length is shorter and populations grow more rapidly. There is thus a trade-off between terminal additions and acceleration of maturation. Delayed maturation caused by terminal addition of a novel trait is selectively favorable only if the benefit of the novel trait is greater than the loss in fecundity due to the resulting prolonged generation length.

Shortening of generation length may be realized by eliminating unnecessary traits or by gradually shortening early developmental stages. Such gradual shortening of developmental stages is called condensation in the literature on evolution (the term "condensation" is also used

in psychology, but with a different meaning).

Condensation and terminal addition act simultaneously and independently. Thus even if generation length increases—the most common trend—condensation may simultaneously have been at work. This implies that it is difficult to separate out and individually observe or measure the two processes. However, in the lineage of humans, condensation is indirectly revealed even by superficial analysis of the diagram in Figure 1. With time, all points in the diagram are displaced to the right, but due to the logarithmic form of the time scale, at unequal distances in the diagram. Therefore, linearity would not prevail unless the points were simultaneously displaced downwards at an appropriate rate. This reasoning rests on the assumption that the pattern will persist, because it is very improbable that it should appear just in our own time. I presume that the displacement of the traits towards earlier ages is accomplished by condensation, a conclusion that, in the case of biological evolution, is made plausible by the general selection pressure discussed above. The model also predicts the action of condensation in the cultural realm, and this subject will be explicitly discussed later in this paper.

One may conclude that the condensation of an evolutionarily old trait, appearing early in development, is less than that of a more recent trait appearing later in development. This seems reasonable, since one may assume that condensation of a specific trait is harder to accomplish the more condensed the trait has already become. Actually, mathematical analysis of the pattern revealed in Figure 1 (Ekstig 1985) indicates that the rate of condensation for a particular trait is inversely proportional to the age of the trait. For instance, the condensation of the development of the embryonic heart is 3% over 10 million years, while Newtonian science is condensed at a rate of 5% per decade. Thus, according to the present model, condensation of the manifestations of memes is about one million times faster than that of genes. This does not imply a claim to measure the rate of the evolutionary process; it only indicates the relative rates of change of biological and cultural evolution.

4. Parallels in cultural evolution

This study will attempt to apply concepts that have emerged from a biological interpretation of the pattern in Figure 1 to the evolution of human culture. Therefore, my analysis of cultural evolution will bring the child's mental development to the fore and examine how successive changes in the child's developmental program are initiated by different modes of selection pressures and how they add up to evolutionary changes.

A conspicuous feature of the pattern in Figure 1 is that it includes the realm of cultural evolution, forming a continuous extension of the trend established by biological evolution. Indeed, just because organic change happens so slowly, compared to cultural change, as to be imperceptible over human time scales, it does not mean that biological evolution does not proceed simultaneously with cultural evolution. Cultural evolution comprises the cumulative development of many cultural manifestations involved in complicated interactions. Nevertheless, a few of the multifarious traits, namely cumulative traits associated with language and science, form the pattern. Other well-known cultural manifestations, such as mythologies, religions, and political ideologies, are not relevant to this discussion since they are not cumulative.

The selected traits exhibit parallels between their manifestation in the individual developmental process and in cultural history. This point is crucial to present model. Consider the ability to perform arithmetic calculations using whole numbers. This faculty emerged several thousand years ago and was later developed into the ability to handle the more sophisticated rational numbers. For an individual human it was and still is necessary first to be acquainted with whole numbers. As a matter of fact, it is generally impossible to omit a former stage of mathematical knowledge before acquiring a latter one, nor is it possible to study math issues in reverse order. This is characteristic of cumulative cultural traits. Therefore, the individual acquisition of these stages follows the same order in which the corresponding stages are observed to appear in the historic record. This cumulative characteristic is not related to psychology, education, or any other external factors, but is a logical necessity inherent in many mathematical concepts. It is only in cultural features possessing cumulative developmental stages, I repeat, that one can expect to find such parallels.

Not all stages of mathematical development, however, are strictly cumulative in the present sense. Thus negative numbers can be acquired somewhat earlier by modern youths than could be expected from their first appearance in history. This illustrates the fact that the points in the diagram are not arbitrary, but are selected according to the criterion of being cumulative.

During the course of cultural evolution new cumulative cultural manifestations are added to the individual's developmental program analogously to the way terminal additions are added in biological evolution. Thus the time needed for a child's mental growth has increased, and this can be broadly verified by referring to the evolutionary record. The infants of chimpanzees, to whom our ancestors are supposed to be related, reach adulthood faster than human children do. Relying on the continuity of the evolutionary process, this indicates that human childhood — viewed from a long-term perspective — has grown longer.

Simultaneously, according to our present approach, condensation has been acting on many cultural traits acquired before maturation, resulting in a continuous shortening of cumulative cultural stages. This hypothesis will be discussed with specific reference to the evolution of language and of science.

5. The evolution of language

Noam Chomsky is reluctant to accept a Darwinian interpretation of the evolution of language, and instead suggests that an inherited universal grammar is the crucial, operative concept. Gould concurs, and further contends that “the universals of language are so different from anything else in nature... , that origin rather than as a simple advance in continuity from ancestral grunts and gestures, seems indicated” (Gould 1989, p. 14). Dennett (1995, pp. 384-400), however, vehemently rejects such non-Darwinian explanations. In considering language as an instinct, Steven Pinker tentatively approaches natural selection in suggesting that if language is like other instincts, it presumably evolved by natural selection (Pinker 1994, pp. 354–355).

Terence Deacon (1997) has articulated a more comprehensive Darwinian framework in his analysis of the evolution of language; I will take this as a point of departure for my discussion. Deacon accentuates the role of development by stating that children are the vehicle by which a

language gets reproduced (*ibid.*, p. 109), and that “the structure of a language is under intense selection because in its reproduction from generation to generation, it must pass through a narrow bottleneck: children’s minds. ... Language operations that can be learned quickly and easily by children will tend to get passed on to the next generation more effectively and more intact than those that are difficult to learn. So, languages should change through history in ways that tend to conform to children’s expectations; those that employ a more kid-friendly logic should come to outnumber and replace those that don’t” (*ibid.*, p. 110).

Deacon indicates the existence of a mutual adaptation between language and humans, children in particular, in declaring that, “we should not be surprised to find complex human adaptations to language on the one hand, whose purpose is to ensure that language is successfully replicated and passed from host to host, and language adaptations to children on the other, whose purpose is to make languages particularly ‘infective’ as early as possible in human development” (*ibid.*, p. 113). He thus arrives at a notion of language as an autonomous process: “The evolution of symbolic communication ... created a mode of extrabiological inheritance with a particularly powerful and complex character, and with a sort of autonomous life of its own” (*ibid.*, p. 409).

If we assume that such an autonomous language has evolved as a result of some kind of selection process, we must make intelligible the very basis of such a selection principle. To this end we may take hold of Susan Blackmore’s suggestion: “I have assumed that people will both preferentially copy and preferentially mate with people with the best memes — in this case the best language” (Blackmore 1999, p. 104). Blackmore’s assumption thus implies two kinds of selection, one acting directly through imitation, a central principle in her works on memetics, and one through sexual selection.

I will now discuss these ideas in light of the present model, and attempt to distinguish between two particular evolutionary mechanisms. The first mechanism comprises the reproductive benefits induced by language, in other words, language as evolved by natural selection. The second comprises the mechanisms that might have caused language to evolve without reference to any influence on the genes of the host, the speaking human. As a consequence of these, I will introduce a third mechanism that has to do with the time children have available for learning.

The existence of the first mechanism is commonly accepted. It is associated with conventional natural selection and thus coupled to genetic changes, in particular those implying the growth of the human brain. I would like to be more specific about natural selection. Following Blackmore, I think that in the case of language, sexual selection is the most powerful mechanism; I will outline this view as follows.

By and large, an adult of high verbal ability will gain a high social ranking. Such people are supposed to enjoy more frequent access to mates and certainly also better access to food and other necessities of survival. In other words, they have greater reproductive success than the average citizen. But such high verbal ability is made possible by a genetically determined high brain capacity, and hence the selection on behalf of language also benefits genes for great brain capacity. In Deacon’s words: “The remarkable expansion of the brain that took place in human evolution ... was not the cause of symbolic language but a consequence of it” (Deacon 1997, p. 340).

In attempting to tackle the question of language evolution in terms of memes, Susan Blackmore has apparently come up with a similar line of reasoning. She suggests what she calls a memegene co-evolution that functions as follows. People are assumed to mate preferentially with those possessing the best language ability. “These people then pass on genetically whatever it was about their brains that made them good at copying these particularly successful sounds. In this way, brains gradually become better and better able to make just these sounds” (Blackmore 1999, p. 104, emphasis in the original).

Of course, other factors quite independent of language contribute to the selection pressure for a large brain, factors such as skill at hunting, foraging, tool making, and warfare. These are mainly coupled to natural selection and contribute to the co-evolution of language and the brain. Actually, one must assume that such abilities were the target of selection for increased brain capacity before humans crossed the symbolic threshold, to use Deacon’s terminology.

My second item, language evolution without reference to influence on genes, brings us back to Blackmore’s suggestion that language is acquired by imitation. The important point in this view is that one must assume that the best speakers have the greatest impact. In other words, imitation implies a process of selection: the best speakers are selected as models.

This process is most important in children’s learning. In their imitative activities, children are strongly influenced by peers with more developed language ability, in particular by older children. But of course, children predominantly learn from their parents and this circular coupling, parents-children-parents, opens up the possibility of an additional mechanism that I will call feedback.

Let us imagine a human being at the dawn of humankind who is endowed with a somewhat better than average talent for the primitive spoken language of the time. This person probably influenced his or her children such that they acquired language more efficiently than did other children. When these children became parents the process was repeated, but, as one may assume, at a somewhat higher level. Such positive feedback improves the language ability of those participating in it. Of course, one can also imagine a negative feedback process having a corresponding opposite effect. Thus, although not having any direct total effect on the evolutionary rate of change, such feedback affects the degree of variation in language ability that, in a second step, influences the rate of change as follows.

Every feature exhibits a certain variation, formed as a Gaussian clock curve, as measured with regard to its fitness in the actual environment. Natural selection works on this variation both by favoring the best-fit features and by disfavoring the less fit. In this way, the clock curve is successively displaced, which illustrates the continuity of evolutionary change. Obviously, the selection pressure is stronger the more a feature deviates from the mean value, and this has an important bearing on the functioning of the discussed feedback process in the evolution of language. Both the positive and the negative feedback processes contribute to broadening the distribution curve of language ability. However, since the selection pressure is strongest on the most deviating features, such broadening will strengthen the selection pressure. So when considering the evolution of language as a selection process at which people preferentially copy those with the best language, we may conclude that the feedback process will increase the pace

of evolution towards higher language ability.

The suggested feedback process differs somewhat from what is characteristic of feedback circuits. In an electronic amplifier, say, a limited part of the output signal is fed back to the input of the same unit and causes a reinforced amplification. In the feedback that reinforces the evolution of language, the information is fed back to children in the next generation, and thus not to the same “unit.” However, to label the suggested mechanism as feedback is legitimate, I think, because of the otherwise great similarity in function.

Of course, someone could object that other animals’ ordinary reproductive processes also involve such feedback in the transition from parent to offspring. However, I think that the difference lies in the learning process human children undergo in childhood. This learning process enhances parental influence and it is that very process that may be seen as analogous to amplification in electronic amplifiers, whereas in animals the offspring’s behavior is determined mainly by its genetically unchangeable constitution.

Before leaving the discussion of the evolution of language I will suggest a third process that is a consequence of the mechanisms so far discussed. As we have seen, these mechanisms imply enhanced childhood learning and thus earlier language acquisition. This contributes to the evolution of language as follows. By acquiring language earlier in life the child will have more time to practice talking before adulthood, hence improving its verbal competence as an adult.

To sum up, there are two categories of mechanisms that I believe underlie the evolution of language. The first is the co-evolution of language and the brain, and this has an impact on genes. This mechanism works mainly through sexual selection. The second mechanism has no direct impact on genes, but works through imitation and an associated selection process. In addition to this selection process I have suggested a feedback process that either enhances or weakens parental influence, thus reinforcing the selection pressure and increasing of the rate of evolutionary change in favor of higher language ability. Finally, I have proposed a third mechanism according to which the enhanced and hence earlier acquisition of language lengthens the time children have available for learning. This mechanism would also contribute to increasing of the rate of evolutionary change.

The suggested processes are mutually reinforcing, resulting in progressively enhanced language sophistication. They also demonstrate the importance of children’s learning for the evolution of language, thus supporting the present model of condensation as an intrinsic principle of all evolution.

6. The evolution of science

Let us now examine the most recent phase of cultural evolution, the evolution of science. I use the word science to refer to the natural sciences, including mathematics.

There is a widespread notion that science evolves in a way analogous to biological evolution. Thus Hull (1988) suggests that scientific ideas develop in lineages in an evolutionary process. A similar notion is expressed by Plotkin (1993), in his discussion of science as a product of a

“Darwin machine.”

Holton and Brush (1985, p. 196), in their cogent account of the evolution of scientific concepts, analyze the analogies between the biological and scientific evolutionary processes in a most clarifying way. These authors compare the evolutionary mechanisms of species and those of science, finding four common points.

First, both processes presuppose continuity. This means that a species or a science can persist only if there is some stable means for handing on its structure from generation to generation. In science this continuity is identified as the operational and quantitative nature of concepts.

Second, there is the mechanism of mutation, the opportunities for individual variations. In science, these variations are assured by the boundless creativity of the human mind.

Third, there is the mechanism of multiplicity of effort. Science and species alike must rely on a large number of individual attempts from which ultimately come those few that turn out to be useful. The innumerable pages of scientific research documentation of past years testify to the wastefulness of this process.

Fourth, scientific theories are subject to a selection process not unlike Darwinian selection acting on mutant forms. Scientists create a multitude of competing theories and concepts; these are subject to tests in which the internal rules of science are applied, as are external conditions such as applicability, potential for further development, or contribution to social welfare.

It must be emphasized that the type of selection acting on concepts is not coupled to selection acting on human genes. In other words, there is no coupling between scientific ability and reproductive success, as we posited in the case of language. A scientist does not give birth to more children than the average citizen. I therefore conclude that the leash between genes and culture, to use Edward Wilson’s oft-cited metaphor, is broken as far as the scientific part of culture is concerned. Another consideration is that science has only been in existence for a few thousand years, too short a time to have had any influence on genes.

Though the similarities between scientific and biological evolution as discussed in the cited literature are descriptive analogies, that does not mean that they lack explanatory power. Selection in particular is commonly regarded as the decisive cause of scientific progress. In our own time such selection is intentional, performed mostly by scientists themselves. However, I doubt that such intentional selection was really operative in earlier epochs during which scientific thinking was tentatively forming its own character.

If one wants to posit a non-intentional selection process acting on the early evolution of science, one must pose the critical question: who would benefit from this selection? Since the benefit cannot be for the genes, the remaining possibility is that science has evolved to its own advantage, an idea in line with the notion of how memes work.

When humans passed the threshold of the symbolic, they obviously increased their ability to imagine abstract concepts. But in mathematics and science the employment of abstract thinking

is still more accentuated, mathematics being totally abstract. The fact that we nevertheless put considerable effort into these activities shows, I believe, that such conceptual thinking must have increasingly attracted people. It must have been, as it still is, irresistibly attractive to the human mind to create the abstract conceptions that have led to the metaphysical notions of mythologies and religions, as well as to the logical and rational explanations of natural phenomena that have led to science. Deacon (1997, p. 421) reminds us in this context of the story of Archimedes running naked through the streets yelling “Eureka!” This myth illustrates the fascinating experience of recoding a familiar observation into abstract scientific concepts, and I think such experiences have had vital influence on the evolution of scientific thinking. Even more importantly, children’s minds must also have developed such a fascination in understanding abstract concepts.

We find another approach to selection in the reasoning Terence Deacon applies to the case of language. Regarding science, we may tentatively infer that scientific concepts are under intense selection pressure: in their reproduction from generation to generation, they must pass through a narrow bottleneck — children’s minds. Scientific concepts that can be learned quickly and easily by children and adolescents will tend to get passed on to the next generation more effectively and more intact than those that are more difficult to learn. For example, we may consider the invention of the position system that made arithmetic calculations much easier. This efficient although more abstract system quickly replaced the Roman way of denoting numbers and thus contributed to the evolution of mathematics.

Scientific concepts are, I believe, typical memes and as such must have proliferated because they are attractive to the human mind. This is also selectively advantageous for their own reproduction in their specific environment, the human brain. In this enterprise they have continuously been exposed to competition with other memes, most pronouncedly, with those of religion. It is thought provoking to interpret White’s (1896) classic account of the “warfare” — to use his own word — between science and religion as a struggle between memes.

The discussed process works by adapting concepts to children’s learning abilities and also, possibly, by adapting teaching content and practices in view of the requirements imposed by science itself. As a result, the learning of specific scientific concepts is being accomplished at successively earlier ages. In other words, our discussion supports the notion, as predicted in the present model, of the condensation of scientific concepts.

Let us discuss a second example. Euclidian geometry in its original form has been taught to children for about two thousand years. Nowadays in many countries such axiomatic geometry is replaced by abridged versions. This is because children can generally learn such a simplified geometry in less time, allowing room in the curricula for other parts of mathematics that have developed in the meantime and are considered as more important.

Earlier learning enables young adults to begin contributing to scientific knowledge from an earlier age, and hence contribute for a greater total time. These people will thus exert a greater than average impact on the growth of science and, presumably, on education.

The accumulation of concepts is equivalent to the terminal addition that we discussed in the case of biological evolution. By and large, this process causes a prolonged learning period in spite of

the superimposed action of condensation.

It should be noted that the present model does not claim to cover the modern phase of scientific evolution, i.e., the last three hundred years or so. In our own time, however, a school system has been developed with the explicit purpose of, among other things, enhancing science learning. Moreover, recognition of the importance of science education has in recent years resulted in the development of the specific research disciplines of mathematics and science education, the aim of which is to improve instruction methods and thereby, of course, learning. Extensive educational projects with such a purpose have been developed, such as Project 2061 (AAAS 1989). No doubt, the school system has strongly enhanced concept learning in science, presumably also causing a rapid increase of condensation.

To sum up this discussion of the evolution of science, in addition to the general notion of intentional selection, for earlier epochs of science history I have suggested two co-operative mechanisms for the selection process. The first is a self-selection of scientific concepts for their own benefit in their own environment, the human brain. This can be considered a memetic explanation. The second is related to the way children and adolescents acquire scientific concepts, implying an adaptation of concepts to those most easily learned. This second mechanism leads to earlier acquisition, thus extending the individual's active period as scientist, and hence contributing to the progress of evolution.

7. Summary

Analysis of various manifestations of evolutionary processes in the human lineage indicates some common principles. One such principle is the crucial impact of development as manifested in embryonic development, in the verbal development of the child, and in the conceptual development of the adolescent mind. These developmental processes are characterized by a specific kind of trait, cumulative traits, which turn out to reveal a pattern that unites the evolutionary process in its biological, verbal, and scientific manifestations. This pattern is a consequence of condensation, a regular shortening of developmental stages. An explication of condensation remains to be made.

The present model shares central ideas with universal Darwinism in as much as it points out mechanisms common to both the biological and cultural realms of evolution. In so doing it also demonstrates the explanatory power of the notion of the meme, since symbols and concepts, as typical memes, are the cornerstones of culture. There is another, somewhat more speculative conclusion. If the observed trend toward the condensation of developmental stages, maintained since the emergence of early life, is not to be broken in our own time, the continued improvement of science and mathematics education is imperative.

I have also discussed several principles for the selection of information to be transmitted between generations in the various manifestations of the evolutionary process. Biological evolution employs natural selection of genetic information. As to the evolution of language, I suggest a process of selection acting cooperatively on both genes and memes. Finally, in the evolution of science, I conjecture that early in the evolution of science memetic selection was in charge, while in our own time we humans have taken over, and carry out an intentional selection. This

sequence of principles of selection should be regarded in the light of the pattern visible in Figure 1, whereby one can perceive how the various principles of selection have contributed to the steadily increasing rate of evolutionary change.

A JUSTIFICATION OF SOCIETAL ALTRUISM ACCORDING TO THE MEMETIC APPLICATION OF HAMILTON'S RULE

By
John R. Evers

I. Introduction: Genes and Altruism

Charles Darwin described the sterility of certain castes of social insects, and more generally, the reproductive self-sacrifice such organisms represented, as "one special difficulty, which at first appeared to me insuperable, and actually fatal to my whole theory." [1] In the 1960's, W.D. Hamilton "inaugurated" the theory of "kin selection," which offered a brilliantly simple explanation for such altruistic behavior. [2] As Holldobler and Wilson explain, "Hamilton recognized the importance of a measure he called *inclusive fitness*, which incorporates both the individual's personal reproduction (classical fitness) and its influence on the reproduction of collateral relatives." [3]

The essentials of kin selection and inclusive fitness are summarized according to a simple equation, called "Hamilton's Rule," which is expressed: $C/B < b$. "This says that the cost C (which is the loss in expected personal reproductive success through the self-sacrificing behavior) divided by the benefit B (the increase in the relatives' expected reproductive success) must be less than b , the probability that the relatives have the same allele," [4] if the altruist gene is to survive natural selection.

Inclusive fitness begins by focusing solely at the level of the gene, but then widens that focus to encompass the entire group or population comprising any given gene's extant copy-set. For example, assume organism X is a carrier of gene- A and that gene- A causes X to behave in a certain way which kills X prior to the production of any offspring. If X 's suicidal behavior directly enhances the survival and reproductive potential of X 's siblings, gene- A still has a chance at survival and even proliferation - not in X or X 's non-existent offspring, but in X 's siblings and their offspring since at least some of X 's siblings will carry copies of gene- A . One copy of gene- A is just as good as the next; any single gene-copy is just as transitory as the organism which carries it. [5] Indeed, inclusive fitness demonstrates that the true fundamental unit of natural selection is a gene's entire copy-set.

For this reason, in the expression $C/B < b$, everything hinges on b - the probability that the altruist's siblings carry copies of the same altruist gene. As Dawkins observed, "[k]in selection accounts for within-family altruism; the closer the relationship, the stronger the selection." [6] Thus, the "family" is merely a short-hand approximation of a representative portion of any given gene's copy-set (according to the degree of relation within the family), and changing degrees of relatedness will directly affect levels of intra-family altruism. [7]

The obvious limitation of Hamilton's Rule is that it only justifies altruism expressed within the family. Alternative theories, such as reciprocal altruism, can account for the natural selection of generally cooperative behavior regardless of familial relationships, but theories such as reciprocal altruism do not necessarily account for altruism. [8] As Wright points out, "[reciprocal

altruism] doesn't involve sacrifice for anyone who doesn't ultimately reciprocate." [9] Hence, reciprocal altruism does not account for "sacrifice" at all. For the purposes of this analysis, an organism that is to be considered an "altruist" must suffer a *net cost* (in terms of reproductive potential) as a result of its behavior, as it was primarily this feature that established the monumental problem which challenged Darwin in 1859 and which was solved in part by Hamilton's Rule.

The intra-family limitation of Hamilton's Rule is a result of a certain feature of genetic reproduction; namely, that genes can only produce copies by making new carrier organisms in which to house these copies. In other words, gene copies are only distributed *vertically* (down family trees) within a population. Because genes distribute their copies in this fashion, the only easily identifiable groups of organisms that will have some *a priori* reason for possessing high *b* values in Hamilton's Rule is the genetic family. Thus, while Hamilton's Rule may have solved the paradox of completely self-sacrificial behavior within the confines of the genetic family, it simultaneously precludes the possibility of altruism directed beyond the genetic family since it is unlikely that a random, non-family member will share a copy of the relevant altruistic gene. When C/B is less than *b*, self-sacrificing behavior can be seen as successful altruism; but, when C/B is greater than *b*, the same behavior begins to look more like genetic suicide. In fact, altruism of any degree should face the threat of competitive elimination where the *b*-value is zero.

Moreover, any benefit enjoyed by an organism not carrying the altruist gene (a "non-carrier") will necessarily dilute the net benefit that would otherwise accrue to the altruist gene's copy-set. Therefore, if an altruist gene is to succeed, some mechanism must evolve which can eliminate (or, at least, offset) this potential dilution. By functioning to decrease any potential benefit to competitors and increase potential benefit to the altruist gene's copy-set, this mechanism will manifest itself generally as an increase in competition between carriers of the altruist gene and their non-carrier competitors. Thus, the inverse operation of Hamilton's Rule dictates levels of inter-family competition generally proportional to any degree of intra-family altruism.

However, if some non-genetic unit of natural selection can allow for a sufficiently high *b*-value among non-siblings (i.e., between any randomly selected members of a population), then the threat posed by the inverse operation of Hamilton's Rule is removed. Richard Dawkins introduced the generally accepted name for this alternative unit of natural selection: it is the "meme." [10]

II. Memes and Altruism

Any meme can be defined generally as a *rule of behavior*, encoded by functional neuronal groups or pathways. Behavior is action, whether mental or physical. Ideas such as *tying shoelaces* or *opening a door* represent rules of physical action, i.e., rules of patterned neural-muscular interaction. Concepts such as *apple*, *seven*, or *causality*, represent rules of mental action, or rules of cognition, i.e., rules of patterned neural-neural interaction. Hence, physical movement is governed by memes which represent rules of physical action and thought is governed by memes which represent rules of mental action. [11]

If memes are units of natural selection (allowing for a memetic application of Hamilton's Rule); and, if memes copy horizontally (allowing the "memetic family" to extend beyond the scope of the genetic family); and, if memes can be directly responsible for altruistic behavior, then memetically driven and inclusively fit altruism can extend to the whole of any given (freely communicating) human population according to the mathematical purity of Hamilton's Rule.

A. Memes as units of selection

Most, if not all, models of selection share three basic elements: (1) variability of base units; (2) competition between base units for reproductive resources, or selective pressure; and, (3) selective reproduction (or, selective longevity).[12] Memetic variation is demonstrated by the approximately one trillion (1,000,000,000,000) neurons which make up the average human brain, with the cerebral cortex accounting for at least 50 billion of these nerve cells.[13] Moreover, because anyone who wants to share any idea with another person *must* create a physical substrate for the idea (e.g., language, whether spoken or written), the full scope of memetic variability is most accurately described by combining the subjective knowledge of *each* living human carrier with the full body of extant objective knowledge (e.g., knowledge encoded in books, or computers).

Considering a meme as a discrete neural group or pathway, it follows that memetic competition is fueled by the need for (finite) neurochemical resources and (limited) neural space.[14] That neural patterns or neural groups compete for space and neurochemical resources is not a novel proposition.[15] Thus, memetic competition for the limited space and biochemical resources available in the brain can be restated simply as competition between neurons or functional groups of neurons for *stimulation*.

Rules of behavior which are followed and reinforced to increase the probability of future stimulation are *remembered*. Memes which fail to acquire the necessary resources for reproduction, whether manifested in physiological or non-organic material substrates, will face competitive elimination, i.e., they will be forgotten. Every human activity, from basic cognition to daily "decision-making," can be seen as a process of natural selection during which functional neuronal groups compete to occupy a behavioral (whether mental or physical) niche within a carrier organism's nervous system. Hence, certain memes are selected over others based on the neurochemical characteristics of the underlying neuronal group(s) or pathway(s), as well as their resulting classical and inclusive fitness.

B. Horizontal Memetic Reproduction and Altruistic Memes

The second and third demonstrations, that memes are capable of horizontal reproduction and that memes are capable of encoding altruistic behavior (assuming such behavior exists at all), are easily made as they are both self-evident propositions.

Genetic reproduction occurs through an elaborate process of cellular fusion and the consequential growth and maturation of newly formed carrier organisms. Memetic reproduction occurs through an equally elaborate process of imitation and/or linguistic communication, whereby memes are copied from one nervous system into another. That memes are capable of

horizontal reproduction (i.e., that memes are not limited to copy distribution within genetic families) is a self-evident proposition, provided the recipient of the proposition is not a genetic sibling of the one advancing the proposition. Indeed, any attempt to dispute the proposition that human beings *generally* are capable of sharing ideas is to advance or attempt to share the idea that ideas cannot be shared. Therefore, it is literally beyond argument that memes are capable of horizontal reproduction.

Finally, while genes encode the assembly of polypeptides and thereby transcribe physiological structure, memes represent patterns of neural stimulation and thereby transcribe *behavior*. Therefore, if anything is to be *directly* responsible for altruistic behavior it will be a meme, whether the meme is genetically encoded (i.e., innately acquired), or learned (i.e., environmentally acquired).[16]

III. Memetic Application of Hamilton's Rule

As currently applied, Hamilton's Rule is based solely on the static nature of genetic identity: because an organism's genetic makeup is fixed for the duration of the organism's lifespan, any two organisms will either share a copy of a gene or they will not, and this objective fact is measured according to probability and familial relation. However, since memes are capable of horizontal reproduction (whether through imitation or linguistic communication), it is possible that any meme, including an altruist meme, could express itself in favor of (and, therefore, presumably in the presence of) a non-carrier competitor *and thereby copy itself into the memetic (i.e., neuronal) structure of the competitor*. In short, a competitor directly experiencing the benefits of another's self-sacrifice *might* subsequently imitate such altruistic behavior for no other reason than having experienced such behavior first-hand. Consequently, one should expect various factors (whether genetically encoded, memetically encoded, or both) to evolve throughout a population which would enhance or detract from the probability of such imitation (e.g., empathy, admiration, so-called "open-" or "close-mindedness," etc.).[17] Any given meme or set of memes could likewise evolve various mechanisms to increase the probability of such imitation (e.g., cognitive or psychological appeal, etc.).[18] Hence, it is conceivable that some factor or set of factors could be delineated that would determine the relative *rate of conversion* (from non-carrier-competitor to carrier-clone) for any given meme within a certain population.

This rate of conversion shall be expressed as a new variable, to be added to the right side of Hamilton's Rule since it will operate to increase the likelihood that the beneficiary organism(s) will carry a copy of the same altruistic meme (following the altruistic encounter). Because the rate of conversion will have no application where a beneficiary already carries a copy of the altruist meme, it will only modify the probability that a beneficiary does *not* carry a copy of the altruist meme, which is described by $(1-b)$. Therefore, the memetically adapted Rule is: $C/B = b + c(1-b)$, where the rate of conversion [c] measures the *likelihood that expression of a meme will "infect" a non-carrier and thereby convert the non-carrier into a carrier*.

Operation of this adapted version of Hamilton's Rule can be stated as follows. Assume that there exists a 1/4 (or 25%) degree of memetic relation within an intra-communicating population. Hence, each member of this population shares roughly 1/4 (or 25%) of the same memes. Assume also that a member of this population carries an altruist meme that has a conversion rate of 3/4

(or 75%). Hence, for every four non-carriers, three will be converted into carriers upon contact with the meme. According to these figures, there is a 13/16 (or, 81.25%) chance that expression of this meme in favor of *any* randomly selected member of the population will operate to confer a direct benefit on a representative member of the altruist meme's copy-set. Whether a *net* benefit is likely to be conferred by expression of that meme will depend on comparing this figure with the Cost-Benefit ratio defined by the left side of Hamilton's Rule.

IV. Conclusion

According to the memetic application of Hamilton's Rule, the key factor to success for altruistic behavior is not a high probability of clone status (with regard to the altruistic gene) based on genetic familial relation, but a high probability of clone status (with regard to the altruistic meme), based on a population's horizontal reproductive fertility. Indeed, a highly infectious, altruistic meme (e.g., 80% conversion rate) existing in a small fraction (e.g., 10%) of the population would still enjoy a very high probability (72%) that expression of any copy, in favor of any random member of the population, would serve to benefit that meme's (growing) copy-set (all other things being equal). Assuming acceptable criteria and empirical data can be established to give real meaning to the "rate of conversion" for any given meme, the memetic application of Hamilton's Rule offers a comprehensive justification for general (intra-societal, or intra-cultural) altruism. Meanwhile, it can be said with newfound certainty that purely altruistic behavior is *possible* within any memetically fertile population.

[3] *Id.*

[4] *Id.*

[5] A sequence of nucleotides which dictates the construction of a specific polypeptide can be classified as a "gene," and can be analyzed as being fit or unfit according to natural selection; but, it cannot be called a "survivor." Likewise, a discrete quantum of functionally synchronized neurons can be classified as a "meme," and can be analyzed as being fit or unfit according to natural selection; but, it cannot be called a "survivor." Any particular sequence of nucleotides or quantum of neurons will degrade prior to or contemporaneous with the death of the carrier organism. Indeed, nucleotides and neurons are as much a part of the organism as is any protein, enzyme, cell, organ, or physiological system. The only thing that is *carried* by an organism (in the sense that it can outlast the organism) is the underlying *pattern* of nucleotides or neurons, which exists purely as a speculative construct of subjective consciousness. The concept of the potentially immortal gene/meme can be made to represent a concrete reality only by redefining the functional "gene" or "meme" as the total extant copy-set of any given particular genetic/memetic manifestation, i.e., as a *population* of gene/meme copies. Any individual member of such a population may be transitory, but the population itself can survive indefinitely.

[7] See e.g., Robert Wright, *The Moral Animal* (Vintage Books, 1994), at 164.

[8] See Dawkins, *The Selfish Gene*, supra note 6, pp. 202-233 for explanations of various strategies for cooperation and mutual benefit. See also, Wright, *The Moral Animal*, supra note 7, at pp. 189-209. According to Wright, reciprocal altruism is the only available explanation for inter-family altruism and, therefore, "wins by default." *Id.* at 202.

[9] *The Moral Animal*, supra note 7, at p.207.

[10] *The Selfish Gene*, supra note 6, at p. 192.

[11] A possible third category of action is linguistic action, which represents a means of converting physical action into mental action, i.e., language is movement that encodes thought.

[12] See e.g., Edelman, *Neural Darwinism* (Basic Books, 1987), at p. 9.

[13] Kandel & Schwartz, eds., *Principles of Neural Science* (N.Y.: Elsevier Science Publishing Co., 2nd Ed. 1985), at 223.

[14] It also follows that memes compete for access to the limited and finite materials required for manifestation in non-organic memetic carriers, e.g., book space, computer storage space, etc.

[15] For example, Edelman describes the "Mnemon hypothesis," proposed by J.Z. Young in 1965, which describes a means for selective competition amongst neuronal groups competing for stimulation. (*Neural Darwinism*, supra note ____, at 14-15). Edelman's own theory of neuronal group selection is based on the concept of neuronal competition for stimulation. (*Id.* at pp. 45-46).

[16] For the purposes of this analysis, innate behavior describes behavior which is the immediate result of memetic expression, but which is ultimately the result of genetic expression, i.e., the responsible memes are formed as a result of genetic expression. Learned behavior is the product of environmentally acquired memes which are, in turn, the product of epigenetic, somatic selection. An innately acquired meme that is incapable of horizontal reproduction is the functional equivalent of a gene.

STROLLING THROUGH THE MEMETIC MINE FIELD

By

Leon Felkins

WRITTEN: 28 AUGUST, 1995

REVISED: 9 SEPTEMBER, 1995

INTRODUCTION

Isn't it strange that in the past people were so peculiar in their tastes, their prejudices, their sexual attitudes, their treatment of animals, and their family relationships? Even now, people in some parts of the world have some really strange ideas about how to feel and behave. Were our ancestors stupid? What about the great scientists and philosophers of the past, who seemed very intelligent, yet showed little understanding for the problems of women and minorities? Many of the great leaders and statesmen of the past even had slaves. Are we just smarter now -- or what?

No, those strange folks in other times and other lands were making decisions in the same way you do now -- decisions based on the memes and genes that inhabit their minds.

We all know what genes are, but maybe we are not too clear on "memes". Basically, memes are beliefs that spread from individual to individual; that is, they replicate somewhat as genes do. Note that the concept of "memes" itself is a meme!

In this essay I will give a brief introduction to how the mind is influenced by memes and genes and give examples of the many memes that have great control over our lives.

ME AND MY MIND

While the subject of the mind and exactly how we humans control ourselves is very complex and somewhat controversial, a limited review is possible that will be adequate for the purposes of this essay. (An excellent reference on this subject is [DENN]).

Our mind controls our body somewhat like an operating system controls a computer. While the task of genes is primarily to determine the physical characteristics of our bodies, including our brain and nervous system, they also influence decisions of the mind. For example, the fact that genes make us feel great pleasure in sexual activity certainly has a great influence on the mind.

But the mind is also strongly influenced by beliefs -- and that is where memes come in. In his book, *The Selfish Gene* [DAWK1], Dawkins defines a meme as a replicating information pattern that uses minds to make copies into other minds. That is, memes are thoughts, ideas, beliefs, prejudices, etc. that replicate. Dawkins writes:

"Examples of memes are tunes, ideas, catch-phrases, clothes fashions, ways of making pots or of building arches. Just as genes propagate themselves in the gene pool by leading from body to body via sperm or eggs, so memes propagate themselves in the meme pool by leaping from brain to brain via a process which, in the broad sense, can be called imitation."

(Several good papers on this subject are available on the Internet, for example see [HENS] and [HALE]).

The memes associated with morals are often referred to by the term "mores" which my dictionary defines as, "folkways of central importance accepted without question and embodying the fundamental moral views of a group".

For our purposes here we will assume that the individual's mind makes its decisions by means of analysis of the inputs as augmented by the genes and memes. Details on just how genes and memes influence the mind will be discussed in the next sections.

A comparison to computers may be helpful: Genes correspond to the ROM that is built into computers. Memes correspond to the programs that run on the computers, along with the associated data, and are loaded subsequent to the initial boot. The mind corresponds to the Operating System. Roughly.

Note that the origin of a meme could be based on fact or logical analysis. Memes should not be equated with myths. But the meme once established in the mind is just a belief -- regardless of its origin.

Memes are comparable to genes in the fact that they replicate and that they influence our behavior. But how memes influence the mind is quite different from the way genes do. Let's look at each approach.

Genes

Our genetic psychological factors are powerful forces that tell us what to do but, unfortunately, are slow to adapt to a changing world. Tragically, they are just not adequate for humans interacting with a rapidly changing world. We are struggling today with emotions -- provided by our genes -- appropriate for the caveman.

Genes cause problems because they provide psychological directions for a particular situation that is no longer appropriate. The evolved genetic solutions for certain problems apparently worked at one time but may no longer do the job. Unfortunately, it takes thousands of years for the genes to be modified.

Genes affect our behavior in two ways: physical characteristics and sensual enhancement.

Physical Characteristics

Many of the characteristics of humans, both physical and mental, are determined at birth. We all are unique when it comes to capabilities, emotions, and physical makeup. One person's sexual drive can be as different from another's as their ability to play music or do mathematics is.

Sensual Enhancement

Our physical characteristics, our hormonal makeup, and our other inherited factors color the sensations sent to the brain from which it must make decisions. That is, from a given set of external conditions, the message received by the brain is not the same for every individual. Moreover, the brain's ability to process these messages is vastly different from individual to individual. Therefore the decision made by two different brains, based on the same external conditions, could, and likely will, be quite different for two different individuals.

Now, to complicate the matter further, the memes get involved.

Memes

To the brain, memes are additional facts that are combined with the genetic input (discussed above) from which a decision is made. Even though they are just beliefs, for all practical purposes to the brain they are facts.

For efficiency, beliefs are accepted as factual and the brain moves on. If this approach were not taken, our brain would get bogged down in analysis to the point that it would never be able to make a timely decision.

Unlike genes, these memes, or "facts on file", may be added, removed or changed many times in a person's life time. The ability for humans to rapidly change our society and our surrounding environment, made it necessary for some adaptive mechanism to be built in our mind that would allow for these rapid societal and environment changes.

As we noted above, memes are more effective than genes in dealing with modern problems due to their ability to rapidly develop. That is, while genetic forces have evolved over many centuries to adapt to particular problems, memes can evolve in a lifetime or less. The price to pay for this quick reaction is that there is little chance for corrections when the memes may be in error. In fact, the behavior they evoke is not necessarily best for humans (but may be best for the memes - see [DAWK2]). They just evolve, mainly based on short term phenomena, limited information and often, ignorance.

Unfortunately, memes generate psychological forces and emotions that are just as powerful as genetic forces. Sexual mores, to be discussed shortly, best illustrate the power of memes.

It is difficult for each of us to make decisions without using memes. Since memes are involved in our thinking process, we may have to use memes to evaluate other memes! Even when applying our best effort to think precisely and logically, we may still be basing our decision on "facts" that are really just memes. After all, the "scientific method" itself is a meme.

How Memes get established

Memes can evolve spontaneously in a group in response to some problem. That is, the meme evolves, somewhat like genes, by adapting to conditions and continuously changing. Most likely

our meme for compassion probably evolved this way since it made life better for everyone in the group.

It is obvious, however, that many memes are "planted" in the group by certain individuals for their own reasons. The politicians, the schools, the press, the clergy and others are guilty of sowing a constant stream of memes within the populace and encouraging their growth. Examples will be given in the next few paragraphs.

Just like genes, the survivability of a meme depends on its environment. In that sense, memes that are compatible support each other's growth and survivability. The meme for religion, for examples, is helped a great deal by the meme that says we should have "blind faith".

Yet, strangely, we do harbor contradictory memes.

Contradictory Memes coexist

Since we are constantly bombarded with either new memes or the reinforcement of old memes, it should be no surprise that many of the memes might be contradictory to each other. What is a surprise is that humans seem to be able to have contradictory memes cohabiting within their mind at the same time! An example would be a person who works with computers using analysis and logic all day and yet has many beliefs in religion and sex that he accepts on blind faith.

Now let us look at how memes and genes work together to get us to do their bidding. See [DAWK1], page 192.

The Gene/Meme Team

It appears that memes enhance or amplify the influence of genes in many situations. For example, genes insure that a young man is sexually excited when he views a young voluptuous girl in the nude. Memes, on the other hand, might make this young girl even more attractive *with clothes on* if she were only *partially* clothed; or if she is his best friend's wife; or if she admits having just had sex with someone else; or she is seen buying porno flicks; etc.

Practically, the gene/meme team determines our outlook and our attitudes toward the world.

Our Individual World View

The genes we have inherited and the memes that we have adopted determine what our world view is. They provide the perspective in which we view the world and the basis for our decisions. It is ridiculous for us to make judgments on how other people act in other times or other societies. For our judgments are based on our set of memes, and their actions were caused by their set of memes. Our memes are not superior just because we happen to possess them.

We simply should not be critical of other societies based on nothing more than our own meme/gene makeup. For example, to judge that societies in which marriages are arranged or

where free love is common are inferior to ours is stupid. They live by their memes and we live by ours. That's all.

In fact, it is important to keep in mind that any judgment you make about anything is directly based on -- or at least contaminated by -- memes and genes. Even your opinion of this essay comes from a foundation of memes that this essay may be critical of! So, could you just turn off your memes until you finish reading this article please! Just kidding.

Logical Thinking

Can we think without being influenced by memes and genes? While we can't completely eliminate the influence of memes and genes we certainly can diminish their impact. Further, we can adopt the "Scientific Method" which requires that all conclusions be subject to verification. That is, we can keep an open mind for errors in our thinking and try to minimize accepting anything on blind faith.

THE MEMETIC MINE FIELD

In this section I will list some of the common memes we live with. It is difficult not to pass judgment on some of these memes as many appear not to be in the best interests of our society. But the primary purpose here is to list the memes, not to judge them. Let's start with the richest source of funky memes -- our love life!

Sex, Love, Marriage

"Sex is Immoral outside of Marriage"

This well known, apparently religious based, meme is blindly followed by many people who aren't even into religion! Many people feel guilt if they have sex outside of marriage and have given little thought to the origin of that feeling.

Relations between the Sexes

There is always a great deal of memetic activity in this area!

Sexual Harassment

There is no doubt that humans, particularly men, have done some pretty heartless and cruel things to members of the opposite sex just to get sexual favors. To combat this problem, laws have been passed and memes have been established. Both, unfortunately, have gone too far.

The current "sexual harassment" meme now deems sexual harassment what used to be harmless and entertaining sexual flirtation between the sexes. Apparently this meme can be turned on or off since some women admit that the actions that would be deemed "sexual harassment" in one situation might be deemed "desirable flirting" in another.

It is interesting that in the past, for a man to have refrained from flirting would have hurt some women's feelings due to the sexual meme that they possessed then.

Male/Female Relationships

This essay is far too short to cover all the memes alive and well in this area! Instead I will only discuss the prejudicial memes and that will be done below in the "Prejudices" section.

Death

Funerals and other ceremonies surrounding a death are powerful and ancient memes that remain unchallenged in the most modern of communities. The United States has spent millions retrieving the bones of service men and others from foreign countries without a thought as to what could be in those bones that make them so valuable.

Cleanliness

The meme that makes us want to be forever spotlessly clean probably, on balance, is a good one but does get a bit silly at times. Lovers, husband and wives, etc. refuse to share a tooth brush but otherwise swap bodily fluids with abandonment!

Even people who actively support environmental causes still insist on a shower and clean clothes everyday without the tiniest consideration of a rational justification for wasting energy on a somewhat fastidious purpose.

Politics and Government

There are too many memes associated with government to enumerate. I will mention a couple, not necessarily the most important.

"The government can fix all our problems"

This powerful political meme causes all of us a lot of grief and expense. In reality, it is quite rare that government ever solves any problems without creating far greater ones, and, at the same time, relieving the taxpayers from a lot of their money. The fact that government has been so successful in instilling this meme in most of the population and in keeping it alive (in spite of all evidence of their success to the contrary), is quite astounding!

"Let the government pay for it"

Another meme that the government has been very successful in establishing is that they can provide services for free. How often do you hear someone say, "It doesn't cost anything - the government is paying for it!" Right!

"The Sanctity of Government"

This meme has taken some hits here in the USA in recent times but will probably survive. Recently, President Clinton had to admonish the people that it was wrong to be critical of the government.

Well, maybe so, but a rational person must realize that the government, including law enforcement agencies, is composed of people looking after their own best interests and who, in fact, have a long history of corruption and deceit. We would probably be better off if we simply gave the government the respect it deserves -- based on its record.

"People of Country X are Evil"

During World War II, the Allied countries very successfully implanted the meme in to the minds of the citizens that the Germans and the Japanese were evil monsters. Later, to a lesser degree, the Russians were made to look evil. Of course, in each case, when peace is made the memes have to be squashed quickly! People fight wars better if they hate each other!

"The primary factors for selecting (male) politicians are his sex life (or, more likely, the lack thereof) and how much hair he has"

Strange but true. To be fair, we did accept Clinton and his sexual escapades, but he is a goner if we find out that he is wearing a toupee!

Environment

The "Concern for the Environment" meme is a very interesting meme. Since our genes promote selfishness, without restraint, the genes would likely have us trash the environment. But let us not be too hard on the genes. Their selfishness was established in ancient times before we had the power to lay waste thousands of acres in a day. Again, the genes are not up to handling a modern situation.

So, the solution is to establish memes that tell us that trashing the environment is wrong. This has been amazingly well done by environmentalists and the government with the help of the news media.

Memes, like genes, by necessity are simplistic so as not to take up too much space in our limited brain capacity. We see people making sure their own trash is picked up at a camp site even though there is a huge pile already there! We see people using vast quantities of water for bathing and electricity for air conditioning while religiously making sure that their old newspapers are carried to the recycle depot.

Compassion

Without compassion, civilization, or at least a decent society, would probably collapse. On the other hand, we know that humans have the capability and the tools to be incredibly cruel to each other.

Periodically, we are confronted with the facts that humans will do horrible things to each other -- especially if they are not held accountable. How can this be if we are compassionate?

The answer is that compassion is most likely not genetic. No, compassion is a meme that is grilled into our heads from childhood. Thank goodness for this one!

Cause and Effect

The "Cause and Effect" meme is an interesting one. This meme, established by the scientific revolution, says that most situations, such as health, mental states, relationships, etc., have simple causes. A popular example is, "If you eat the right foods and avoid the wrong foods, you will not get cancer or heart disease".

To be fair to the scientists, the statement "established by the scientific revolution" needs some qualification. Actually the meme is a misunderstanding of scientific principles. Scientists may publish a report that says -- I'm making this up -- that there is a correlation between eating a lot of stale hot-dogs and the loss of sexual desire. The facts may be that people obsessed by sports spend a lot of time in stadiums (where they eat a lot of hot-dogs) and have little time or interest in sex. But the news media simply reports that "hot-dogs kills sexual appetite" and that becomes the meme.

That there is a simple cause and effect relationship for most events in the world is a concept that is not necessarily obvious. Yet, strangely, even people who are hostile towards technology and science still believe in this meme ("if you will just take a handful of Vitamin C pills every day, you will not get a cold").

Prejudices

The dictionary gives several definitions for "prejudice", the first two in mine are:

"1. an unfavorable opinion or feeling formed beforehand or without knowledge, thought, or reason. 2. any preconceived opinion or feeling, either favorable or unfavorable."

A common and well established meme in our society would have us believe that the first definition is the correct one (yes, our prejudice against prejudices is itself a meme). Yet the second one is probably more practical since it would allow "prejudices" to refer to both good and bad beliefs.

However, in recent times, due to the tragedies associated with some unfortunate historical prejudices, a powerful meme has been established that prejudices are bad. Since the crux of the definition of "prejudice", "opinion or feeling formed beforehand or without knowledge, thought, or reason" sounds almost like the definition of a meme, we might simply define a "prejudice" as an unfavorable meme.

So, it appears that prejudices are just a subclass of memes that are believed to be bad. Therein lies a "can of worms" for we are all in possession of thousands of memes and whether they are good or bad is a judgment call (made with the help of another meme!).

Let us look at an example or two. Almost everyone agrees that racial prejudice is bad. How about prejudice against people that seem stupid? Speak with a Southern accent? Wear unstylish clothes, are economically disadvantaged (poor), are fat, and so on?

The fact is prejudices have the same advantages and failings that other memes do. They allow the brain to make a quick judgment which is generally necessary for survival. If the prejudice is based on logic and/or facts (definition number 2), then it is useful. If it based on faith or "opinions without knowledge", like memes in general, then it can be bad.

Let's look at a couple of well known examples:

Racial prejudices

Racial prejudices have caused much grief, cruelty and suffering in the world. Genes may be the culprit here -- in an indirect way. Genes would have us to *only* look after the best interests of those folks that are closely related to us. [DAWK1] People with a different color or from a foreign land certainly don't meet that requirement.

There appears to be some success in diminishing racial prejudice in much of the world. This success is the result of diminishing the control of the "racial prejudice" meme and by establishing another meme that says you are a bad person to have racial prejudices.

Sexual prejudices

Obviously the sexes have some differences. However, it is not conducive to peace and harmony to believe that one sex is inferior to the other. Yet, creating a meme that says there is no difference in the sexes, as some are promoting, seems to be a bad approach. A better meme would be simply "neither sex is inferior to the other".

Cool Sayings and actions

Expressions that are considered "cool" come and go and woe to those who use an out of date one!

An interesting aside here is the survivability of the word "cool" itself. It has been around for a couple of generations.

How about wearing your shoes untied and your baseball cap on backwards?

Advertising

Companies know that getting the right memes established can result in profits of millions of dollars! Trademark and trade name recognition along with the associated belief in superior value is a common and profitable type of meme.

A few months ago, while at a party, a friend of mine was induced to take a blind folded taste test of various bourbon whiskies -- including her favorite that is very pricy (another meme!: "quality equates to price"). To her embarrassment, she flunked the test, picking "Jim Beam" as the best. Did that change her buying habits? Of course not!

Brand name acceptance is a powerful meme that the majority of the people unhesitatingly follow. However, there are recent trends that indicate that people are beginning to drift away from that bias and to try products that have generic labels. Maybe there's hope.

Clothing

An amusing but serious application of memes is our attitudes towards clothing styles. Without any particular reason, clothing styles change with time: skirts get short and skirts get long, ties get fat and then they get slim, and so on.

The "clothing styles" meme allows us to clearly see the power of memes. We genuinely feel negative toward a person dressed in clothes that are "out of style" but were in style some years ago. Now, rationally, we know this is ridiculous. How can there be anything wrong with a style that once was a popular style?

Here we have evidence that memes can make us feel badly towards something that is not supported by rational reasoning -- in other words, prejudice. With this recognition in mind, we might want to reflect on the many other memes we so blindly accept.

Many of our young people truly believe that if they will only buy and wear the right brand of athletic shoes, they will be able to do athletic feats that defy the laws of physics. It is a sad reflection on our society that advertisers have been so successful in planting this meme that really exploits the young, especially the very poorest young.

Food

In some parts of the world people would no more consider eating a cow or a pig than you would a dog.

Music

A real tragedy here. Essentially all varieties of music have at least some examples that are enjoyable and some that are quite outstanding. Yet memes dictate, particularly to the young, what "brand" of music they should "enjoy". And they seem to only enjoy that designated music! Amazing, the power of memes!

Family

Our attitudes towards members of our family are greatly affected by memes. These attitudes vary greatly over time and in different societies. In the 60's, the meme got established, with some justification, I suppose, that parents could not be trusted and were generally out of touch with the activities and interests of the current society. This meme has caused a lot of grief and suffering for everyone and is one that needs to be replaced by something more realistic. How about, "Parents are (reasonably) out of date, a little sluggish with the thinking and may have some interests of their own, but they are all I have and it would be in my best interests to stay on their good side".

Political Correctness

This good intended but rather hopeless meme has had amazing success, particular on the college campuses. The driving force seems to be to eliminate any possibility of unfairness or hurting anyone's feelings. To accomplish this, we are told that one word is better to use than another word, even if they have the same meaning, because the words themselves can hurt. So we are told that "intellectually impaired" is better than "stupid", for example.

In view of the rather outlandish requirements that this series of memes puts on our belief systems, it is doubtful that they will survive. There is a limit to what you can make reasonably intelligent people believe!

Religion

Religion has had a great deal of success with memes. In fact, for anyone wanting to do research on the impact of memes, this is probably your best laboratory. There are many memes associated with religion, of which only a few are listed here. The memes listed here are associated with the Christian religion but in most cases are applicable to all religions.

- Infallibility of the Bible
- If you don't rely totally on blind faith, you are a creep!
- The power of prayer
- Heaven will be your home after this life
- Converting others will help you get to heaven
- Sending your money to God's representatives is what God wants you to do

All of these memes have proven to be very successful in promoting Christianity.

Academia

Much of the discussion above on "Political Correctness" applies to academia. However, there are a few more peculiar memes that thrive in that environment.

Academic Freedom

This well entrenched meme holds that academic freedom is more important than the welfare of the students -- or maybe even the university. During my personal experience as a professor in a public university, no administrator ever sat in my class room to evaluate my capabilities! Instead of Computer Science, I could have been teaching flatulence control (and doing a bad job of it, possibly) for all they cared.

"We need more research to understand the world better"

Poppycok! We need research to promote the selfish interests of the universities and the professors. This meme costs the taxpayers a few bucks!

"Doctoral Dissertations make major contributions to our understanding of the world"
Ha! Go read some of them!

Social Relationships

"We should cooperate"

Social scientists say that the genes would have us look only after our own selfish interests even when cooperating would be better. But, thanks to some powerful memes, most people seem to want to cooperate even when it may not be in their best interests to do so. This behavior is apparently caused by a good meme, the idea that we should cooperate.

"We are all created equal"

Of course, we are not. We do have -- somewhat -- equal protection under the law, but we have vastly different capabilities, most of which result from birth and the circumstances we were born into.

Is this a good meme? Consider this your homework assignment. :-)

TAKING CONTROL

The quite incomplete list of memes presented above constantly and continuously try to control our lives. It is obvious that a few are good but, in my judgment, many are bad. One thing is for certain: it is not in your best interests to totally resign to the control of memes. But can you do anything about it? Certainly.

If we accept that many of our actions are meme based and therefore can be changed, we have the potential to improve our lives by evaluating the memes and overriding those that we believe have the potential to do us harm.

But how do we override memes? They are just as powerful as genes and they color our thinking, right? True, but they can be overridden by applying the rules of logic.

For example, after a person has accepted that certain memes are enhancing or interfering with their love life, that person should examine these memes under the microscope of rigid logic. Up until recently, there was a meme that said it is bad to masturbate. OK, let's take a look at it. What exactly is bad about it? Is there really any correlation between masturbation and our visual difficulties? Not that anyone can prove. Is it sinful? You will have to decide that. What else? Not much. Another meme for the trash!

One useful tool in examining sexual mores is to ask, "What do animals do?" After all, we are part of the animal kingdom and most of our sexual genes are common. But, as far as we know, the rest of the animals are not burdened (or blessed) with sexual memes. Based on this approach, you might ask, for example, is it OK for a female to have several lovers? Looks fairly common amongst the higher mammals. You take it from there. :-)

But be careful. Some rules are not universal in the animal kingdom. For example, monogamy or polygamy; which is normal? No universal agreement here.

By selecting the good memes and chunking the bad ones, you should be able to greatly enhance your life and to avoid dropping a pile of your hard earned cash at the local shrink. Your friends will appreciate it too.

VIRAL MARKETING: SPREAD A COLD, CATCH A CUSTOMER

By

Frank Fiore

The Business Journal of Phoenix - June 25, 1999

They call it "viral marketing." Having someone else spread the word to drive more visitors to your site.

Let's face it. The best kind of marketing is the kind you don't have to do yourself. Especially if you're a small business on the web with a limited advertising budget. Viral marketing is like it sounds. Call it word-of-mouth, spawning, self-propagation -- organic.

Great new idea, right? Nope. Viral marketing has been around forever. Spreading the word through word-of-mouth was the world's first form of marketing. But the Internet has taken this organic form of marketing to new heights by making communications better and communities of people tighter -- thus making word-of-mouth even more effective.

When you use viral marketing as a tool, you're using the Net the way it was meant to be used. Viral marketing on the Net has a long history. The first use was by Netscape. The small "Designed for NETSCAPE" icon was first used as a status symbol by webmasters to show that their site was the latest in web-page design. It didn't take Mr. Gates very long to see the power of viral marketing and soon "Designed for MS Internet Explorer" icons quickly spawned next to Netscape's.

A couple of years later, the creative marketers at Amazon took viral marketing beyond this simple link. When Amazon created the first affiliate program on the Net, they spawned a whole new generation of viral partners eager to promote Amazon's book site to their web-site visitors.

Today, they have more than 100,000 affiliates promoting Amazon and gaining a small commission on each sale directed to them.

Affiliate or associate programs are now one of the hottest viral marketing programs on the web. There are hundreds of small, medium and large companies offering their programs to any web site that wants to earn a few extra bucks.

But you don't have to have a costly or complex affiliate program to use viral marketing in your business. There are other ways to motivate your customers and visitors to do the marketing for you.

Here are just a few.

- Pass this on, will ya: The granddaddy of the new viral marketing has to be HotMail which soon was copied by Yahoo! and anyone else who had a free e-mail service. It was simple. Attach your URL to every e-mail that your users send out. Before they knew it,

HotMail had more e-mail users than the largest ISP. You can do the same. Make sure that every e-mail sent out from your company has your URL on it.

- Tell 'em Sam sent you: Reward your steady visitors for bringing new visitors to your site. Create a special "referrer program" that your steady visitors can sign up for. Have them invite their friends to visit and if they do, have them mention the referee's e-mail address and the referee earns something free from your site.
- I'll scratch your back if you scratch mine: Your site sells cigars. Their site sells humidors. A relationship made in web heaven! Look for sites that sell complementary products or services to your own. Then contact them and offer a reciprocal linking arrangement. You can go even one step further and offer their visitors a discount if they join your referee program.
- Got any good jokes lately?: I don't know how many times I've forwarded jokes or scam and virus alerts I received in my e-mail to friends and associates. So, create a funny newsletter or an e-mail alert that someone would pass on to friends.
- Take my site, please!: This is similar to "Got any good jokes lately" but in this case you give away your best assets. Don't just send out a notice about new content on your site -- send out summaries by e-mail and ask people to forward it on (with copyright and URL attached, of course). A variation on this is to let other sites reprint your content on their site, with appropriate credits and links to yours.
- And the winner is: Create an award for the best sites in your category or subject area. Then send them an e-mail informing them they won the award and where to acquire the award icon to place on their site. I do this with my Mining Co. Online Shopping site.

I award a "Best of the Net" to certain worthy sites and ask them to place the "best of" icon on their site -- which is then linked back to my site.

The one downside to viral marketing is that you're letting others do your marketing for you. Though this will save you money, your message and your brand are in the hands of someone else. There's a fine line here of spreading the word and diluting your brand.

The challenge is to exercise some control of how your message is delivered and how others perceive it. But when you master this technique, your message and your site can spread as quickly as the common cold.

Finally, don't expect a viral marketing program to pay off immediately. Like a real virus, viruses don't become epidemics until they reach critical mass. Your virus must propagate through the host population until it reaches a certain threshold of visibility and scale.

Think of it this way. Suppose a real-world virus doubles every year. In the first few years it's scarcely detectable. But within a few years after that it suddenly becomes an epidemic. You

should understand that you're playing the same game. Viral marketing takes time. So be patient, be fruitful -- and go out and multiply.

CULTURAL R/K SELECTION

By

Agner Fog

Ørnevej 29, 2400 Copenhagen NV, Denmark.

agner@login.dknet.dk

Abstract

A new model of cultural r/k-selection is introduced. This model, which provides a classification of cultural processes based on the factors that influence memetic fitness rather than on selection mechanisms, predicts that cultural evolution will go in different ways depending on the balance between internal and external conflicts of a society. A society dominated by external conflicts or war will evolve in a direction called regal, whereas a society in a peaceful or sparsely populated area will evolve in the opposite direction, called kalyptic. The regal or kalyptic characteristics of a society influence the evolution in many areas of culture, including religion, political structure, art, music, etc.

Key words: r/k-selection, vicarious selection, regal, kalyptic, sociology, religion, art, music, architecture.

1 Introduction

The new model introduced in this article provides a way of explaining important social phenomena based on cultural selection theory. The model is defined in terms of memetic fitness determinants, and some possible mechanisms are outlined. The article finally discusses how the theory can throw new light on human cultural history and contribute to a better understanding of various cultural phenomena, including religion, ideology, art, and music.

It is assumed that the reader is familiar with memetics or cultural selection theory. A popular introduction to this paradigm is given by Lynch [19]. A more thorough description of mechanisms in cultural selection can be found in Boyd & Richerson [5] and Campbell [6]. A more sociologically oriented version of the theory is given by Schmid [30].

The theory presented here is described in more detail in Fog [14].

2 Fitness Determinants

The fitness of a replicator (gene or meme) often depends on several different factors. Some of these factors are important because they are responsible for a large part of the variation in fitness, while other factors are less interesting because they have only little influence on the fitness, or because they do not vary significantly within the boundaries of the system being studied. In systems which are too complex to analyze in detail it may be useful to concentrate on those factors which have the highest effect on fitness. The most important factors define what I call the *main fitness determinants*.

The concept of fitness only makes sense relative to a specified process of reproduction and selection, be it genetic or cultural, and a specific environment. It is important to recognize that fitness is a *relative* concept, depending on the selection mechanism and external conditions. Different selection conditions can lead the process in different directions, and an examination of the fitness determinants is necessary to predict the direction of evolutionary change. The failure to acknowledge this dependency has led to the often criticized unilinear theories of cultural evolution.

In order to illustrate the relativity of the fitness concept, I am going to give an almost classical example: The habit of tobacco smoking has spread to most of the world because it gives a subjective feeling of pleasure and because it is difficult for the smoker to quit when the unfortunate consequences turn up. But smoking undermines the reproductive health in many ways which reduce the probability of producing healthy children (Abel [1] and ARHP [4]). We must therefore conclude that smoking is promoted by cultural selection but counteracted by genetic selection. Tobacco smoking has a positive fitness in cultural selection but a negative fitness in genetic selection. If we pin down the process of cultural selection into partial processes, such as hedonic selection (Martindale [21]), rational selection, economic selection, etc., then we will see that the broad label of cultural selection comprises many different mechanisms each pushing in its own direction. The study of conflicts between different genetic selection mechanisms pushing in different directions has led to important results in sociobiological theory, and a similar study is highly needed in the area of cultural processes.

A fitness determinant is not the same as a selection mechanism, but it is determined by the selection mechanism and in particular by the external conditions and selective forces working on the system. I will explain what I mean by fitness determinants by referring to the example of economic competition. Industrial enterprises may compete to produce the cheapest products of a particular quality. One possible mechanism in this process is that those factories which use the cheapest sources of energy, manpower, and other resources outcompete less efficient producers which then go bankrupt and disappear. A more efficient mechanism is that intelligent managers consciously seek the cheapest resources and production methods, thus avoiding bankruptcy. The latter mechanism is faster than the former, but they both lead the evolution in the same direction because they have the same fitness determinant: cheap production. Knowing the fitness determinants without knowing the mechanism, we may predict the direction of evolution, but not its speed.

3 Classification Based on Fitness Determinants

An analysis of the fitness determinants of a system can be useful for predicting the direction of evolution. This approach is particularly attractive when the system comprises so many complex, and possibly conflicting, selection mechanisms that a detailed mathematical modeling is impossible.

One example of a classification based on fitness determinants is the distinction between specific and general evolution as defined by Marshall Sahlins [28]. Specific evolution is the adaptation to a specific niche, while general evolution is the evolution of *adaptability*. Evolution of specific adaptedness may be advantageous in a constant and stable environment, while the evolution of

general adaptability or flexibility is required in an ever-changing environment. This distinction between specific and general evolution is applicable to biological as well as to cultural evolution.

Another example is the distinction between r- and K-selection in biological evolution (ALexsic [3], Takada [31], Wilson [32]). If an animal species lives under conditions where resources are ample so that there are good opportunities for expansion, but where there are also considerable dangers such as predators, then it will be advantageous for this species to use most of its resources on breeding as fast as possible and spending few resources on each offspring. This is called *r-selection*. The r is the mathematical symbol for the rate of reproduction. r-selection causes the evolution of small animals growing fast and breeding fast. Examples are mice and insects.

The opposite of r-selection is *K-selection*. This is what happens when a species lives under conditions where the population is limited by scarce resources rather than by predation. The capital K is a mathematical symbol for *carrying capacity*, i.e. the maximum number of individuals that the resources in a given habitat can continually sustain. K-selection leads to the evolution of big animals which breed slowly and utilize the given resources optimally, and which invest a considerable proportion of their resources in the care of their sparse offspring. If the animals under these conditions bred excessively, then they would have insufficient resources for nurturing each young, and they might over-exploit their habitat to the point where the resources were exhausted. K-selection is found in those animals that come last in a food-chain, such as whales, elephants, and humans.

The r/K dichotomy is useful for classifying species according to their reproductive strategy. The term *r-strategy* is used to describe animals that use most of their resources on producing as many young as possible, but do not care for their young. The opposite is a *K-strategy*, which means that the animals produce few young but spend a lot of resources on caring for and protecting their sparse offspring. We may expect a species to develop an r-strategy when reproduction rate is the dominating fitness determinant, and a K-strategy when effective utilization of limited resources is more important.

The selection mechanisms leading to these strategies may be more complicated than this simplistic model indicates. In many cases the mechanisms behind K-selection are not fully understood, although the fitness determinants are.

4 Cultural Selection Models

In cultural selection theory, the number of possible models may be greater than for the genetic processes, because innovation, reproduction, and selection of cultural phenomena may involve many different mechanisms and transmission media (Findlay [13], Fog [14]). All these mechanisms may interact with each other in so many complicated ways that a stringent quantitative account and classification of possible cultural processes is hardly possible, and it is even more questionable whether this would be a useful approach in applied social research.

Rather than building a taxonomy of cultural processes on selection mechanisms, I have chosen to base my classification on the social forces that give rise to selection, and the corresponding

fitness determinants. This principle is analogous to the abovementioned distinction between r- and K-selection in genetic evolution.

I am using this shortcut not only to avoid intractable mathematical problems, but also because I consider the direction of evolution more interesting than its speed - and the direction of evolution is indeed determined by fitness. This approach is attractive because it enables you to make predictions about the direction of cultural evolution based on incomplete information about the system (Fog [14]). Of course, I do not deny that other classification principles may have valuable applications.

5 Cultural r- and k-Selection

I want to emphasize that the analogy between genetic and cultural selection cannot be used to prove anything about either mechanism - the differences between the two mechanisms are simply too big (Boy & Richerson [5], Daly [9], Fog [14]) and the reader is warned against expecting too much from the apparent analogy between biological mechanisms and the cultural model presented below. The analogy may be useful as a source of inspiration, and should not be regarded as anything else here when I am introducing what I will call *cultural r- and k-selection*.

Cultural r-selection takes place when a group has substantial opportunities for political and cultural expansion, i.e. to defeat other groups and impose its ideology or culture on them, but at the same time has a great risk of falling victim to the expansion of other groups. In other words, the group is dominated by external conflicts and wars. By group I mean a cluster of people bound together by the feeling of a common collective identity, such as a tribe, a nation state, or a religious sect. Group membership is usually defined by religious, political, or ethnic belonging and is often symbolized by certain distinctive marks (Hogg & Abrams [15]).

Cultural r-selection results in the allocation of a high proportion of the group's resources to the fighting of external wars or conflicts or other collective dangers. The group with the strongest military force and the most effective strategy will win in the process of cultural group selection. In other words, r-selection leads to armament. This armament is not only of a technical kind, but also very much of an ideological and political nature. A strong community spirit will be fostered in connection with an ideology saying that the individual exists for the benefit of the community, that the individual should sacrifice himself for the community, where discipline and uniformity are regarded as virtues, where martyrdom is the highest honor, and where a strong central government is regarded as a sign of wealth. This kind of ideology and a corresponding political organization will make the strongest forces in political as well as ideological conflicts with neighbor groups, and will therefore have the highest cultural fitness in a situation where cultural r-selection is dominating.

The opposite of cultural r-selection is cultural *k-selection*, which takes place when a group has no opportunities for cultural expansion and is not threatened by aggression from other groups. This will typically be the case when a group is geographically isolated, for example on a solitary island, or when the cultural differences between a group and its neighbors are small compared to the internal differences within the group. The external conflicts are small or non-existent and the

only conflicts that are significant in selection processes are group-internal conflicts between leaders and subjects, between subcultures, or between individuals.

A strong military force would be a waste of resources in the absence of external conflicts. The population will not accept a despotic government that unifies and disciplines. They will rebel against powerful leaders, and the fights for freedom for everybody will be the dominating conflicts. This will lead to an ideology where society exists for the benefit of the individual, and not vice versa. There will be more freedom of choice for the individual and higher tolerance towards individual differences. The leaders will regard the life and welfare of any individual as important.

The analogy with genetic r/K-theory becomes apparent when you consider that an r-selected culture spends a high proportion of its resources on winning new territory. Or, to be more exact: The r-memes make their hosts spend many resources on winning new hosts for the same set of memes. The cultural k-strategy implies a different allocation of resources, namely on keeping the hosts you already have by making them satisfied with their society.

The fitness determinant for cultural r-selection may be characterized as military strength and political unification. It is the ability of a culture to spread to new peoples and to withstand the influence from other cultures. The fitness determinant for cultural k-selection, on the other hand, is the contentment of all individuals and thereby a minimization of conflicts between leaders and subjects. Only by satisfying the needs and wishes of all individuals as fully as possible can the culture avoid upheavals. The r-selection is determined by the reproduction of culture in space (geographic expansion), the k-selection is determined by reproduction in time (retention).

In order to avoid the impractical r- and k- terminology and to establish a distance from the flimsy analogy with genetics, I will here introduce the words *regal* and *kalyptic* to replace the symbols r and k in connection with cultural selection. The result of cultural r-selection will be termed a regal culture, and the result of cultural k-selection is called a kalyptic culture. The word regal comes from *rex*, which means king, and I have chosen this word because a dictatorship can be regarded as the prototype of a regal culture. I have formed the word kalyptic from *Kalypso*, the name of a nymph in Greek mythology, who held Odysseus captured on a desert island. This word is chosen because the most typical cultural k-selection is found on isolated islands. You may notice that the K in *genetic* K-selection is capital because the mathematical symbol it implies is so, whereas *cultural* k-selection is written with a small k because it stands for kalyptic. The concept of regal may be delineated by the following definitions:

- a regal selection is a cultural selection process dominated by inter-group conflicts or other collective dangers.
- a regal culture is the result of such a selection, *or*
- a culture which spends a high proportion of its resources on expansion or defense, *or*
- a culture which limits the freedom of the individual members and makes considerable demands on the resources of the individuals for the purpose of strengthening the group.
- a regal cultural product is a cultural phenomenon which is part of the strategy of a regal culture or otherwise a typical product of a regal culture.

The term *kalyptic* is of course defined as the opposite, i.e. a culture which is not dominated by external conflicts, which spends more resources on satisfying the individual than on strengthening the group and which attaches importance to individual freedom. The words should preferably be applied as relative graduations, rather than as absolute ideal types. It makes more sense to say that culture *X* is more regal than culture *Y*, than to just say that culture *X* is regal. I will use the term *regalization* for an evolution in the regal direction, and *kalyptization* for the opposite.

Occasionally, you may observe a correspondence between the strategic implications of genetic and cultural r/k-selection. In a regal society, the population usually spends a lot of resources on producing many children, but invest little in the individual child. In the kalyptic society, people have few children, but spend many resources on giving each child the best possible education. This is in perfect agreement with the *genetic* r- and K-strategies. This similarity between genetic and memetic strategies is due to the fact that I have classified the evolutionary systems according to fitness determinants rather than selection mechanisms. If two different evolutionary systems have similar fitness determinants, then they are likely to evolve in similar directions, no matter how different the selection mechanisms. The concordance between the two systems is far from perfect, though. If a regal culture expands by conquering new territory for its people, then this is in agreement with a genetic r-strategy. But if the regal culture wins new hosts for its memes by proselytizing, then this is an r-strategy only in the context of the cultural scheme, not the genetic.

Due to the weakness of the analogy, I prefer to regard the cultural r/k-model as an independent theory where the r and k do not have the same meaning as in the genetic model, although the similarity in nomenclature is intended.

6 Mechanisms in Cultural r/k-Selection

As explained above, cultural r- and k-selection may be defined by the fitness determinants or driving forces pushing the evolution in one or the other direction. The most important driving forces behind regularization are intergroup conflicts and other collective dangers, while the driving forces behind kalyptization are conflicts within a group, or to be more specific: between leaders and subordinates. However, a driving force is not the same as a mechanism. I will therefore explain some possible mechanisms behind cultural r- and k-selection.

The fundamental factor in regularization is war. A society with strict discipline and an effective controlling of the population will have higher chances of winning a war than a more soft society. The victors are likely to force those political, ideological, and religious principles on the defeated people, that made the strong government possible, and consequently those traits will spread.

It is important to understand, however, that regularization is also possible without war. The *threat* of war is sufficient. The people will soon realize that armament, physically as well as morally, is necessary to meet the threat of war, and the public will have no problems understanding that sacrifices are necessary to defend national security. The cold war and arms race between the USA and the Soviet Union was a clear example of such a reaction. This mechanism is an example of what Campbell calls *vicarious selection* [6]. The rational reaction to the war threat reduces the risk of being attacked as well as the risk of losing a war if it should come. The

cultural result is the same as if they had passively waited for the war: regalization. The vicarious selection works in the same direction as the direct selection, but faster, more effectively, and with fewer costs. Vicarious selection is therefore a very important factor in cultural evolution. Other threats to the society as a whole may also cause regalization, such as mass immigration, economic crisis and overpopulation.

The opposite process, kalyptization, is found among people living in peaceful surroundings. In the absence of external conflicts, the internal conflicts will be the dominating factors determining the direction of cultural evolution. In a competition between alternative political systems, people will prefer the most comfortable, i.e. the one that puts the fewest demands on people and gives the highest freedom and autonomy to the individual. You may call this hedonic selection (Martindale [21]). The population cannot accept a tyrannical dictatorship, and will rebel against excessive concentrations of power. In the absence of other possibilities, the population can vote with their feet: They can simply flee from the regal society to a more kalyptic one. Such an exodus is of course most effective against a small tribe, but also bigger nation states may be influenced in the kalyptic direction by the threat of mass emigration. On the other hand, the emigrants may cause a regalization of the society they invade.

Yet another selection mechanism which may lead in the kalyptic direction is economic and technological competition. A kalyptic society is usually more tolerant towards individual economic initiatives than a regal one. This kind of liberalism provides a better breeding ground for economic growth and increasing material wealth. A k-strategy also involves higher investment in education. This investment pays off in scientific and technological progress. The result of investments in enterprises and education may be that a kalyptic society in the long term will win over a more regal society in the economic competition. During the cold war, the Soviet Union was more regal than the USA, but the latter won because the economic growth and technological progress made possible a superior military technology. The result of this selection process is that American and European culture now floods the former Soviet Union, whereas very little culture diffuses the other way.

These considerations do not, however, mean that economic competition always leads to kalyptization. Economic power and political power are strongly connected, and where economic competition favors large-scale operations the concentration of economic power will also mean a concentration of political power. Much of the *de facto* power will lie in the hands of businessmen rather than democratically elected leaders.

The difference between regal and kalyptic cultures may also be explained as a difference in the *reproductive strategies* of their memes. A regal culture is a culture which utilizes a high proportion of the energy and resources of the individual members in the interest of reproducing its memes. An obvious example is a religion which commands its adherents to proselytize. The missionary work is in the interest of the reproduction of the religion, not the missionary. The strategy of a kalyptic culture is quite different. It gambles on offering its hosts as many advantages and as few burdens as possible. Such a culture spreads by means of the egoistic choice of individuals, in contrast to the regal culture which limits freedom of choice.

The word *strategy* here does not necessarily imply conscious planning. I am using the word in the same way as when biologists talk about the reproductive strategy of a primitive animal or plant having no consciousness. The reproductive strategy of a meme complex is not the same as the strategy of the humans. A cultural pattern which is able to effectively reproduce itself may have arisen by automatic selection of random innovations, or it may be the result of the intelligent planning activity of humans. The selection mechanism works whether humans understand this mechanism or not, and whether this cultural pattern is favorable to its hosts or not.

7 Vicarious Psychological Mechanisms

It is a well-known psychological phenomenon that external dangers to a group strengthen the solidarity within the group and create ethnocentrism and militarism. This phenomenon has been explained as well by evolutionary biologists as by social psychologists.

The biological theories emphasize the importance of group defense, building on kin selection or group selection theory (Lorenz [18], Reynolds &c. [24]).

Within social psychology, the concept of *authoritarian personality* has traditionally been used to explain ethnocentrism and fascism. The characteristics of a person with an authoritarian personality is that he desires a strongly hierarchical power structure and is willing to submit himself to strong authorities, political, ideological and religious. He fears and hates foreigners as well as deviants within his own group, and his morals in religious and sexual matters are strict (Adorno &c. [2]).

Several investigations have demonstrated that those attitudes and behaviors which are characteristic of an authoritarian personality, are promoted by factors which endanger the social order, such as war or economic crisis (Doty &c. [10], McCann & Stewin [22], Padget & Jorgenson [23], Rosenblatt [27], Sales [29]).

Ethologists have explained the mechanism as an infantile reaction: Just like animal young seek protection by their mother when they are afraid, so do adult humans seek protection under a strong leader in case of fear, whereby they become easily indoctrinable (Eibl & Eibesfeldt [12]). This theory has not explained, however, why collective dangers result in reactions different from dangers to the individual.

No matter which intrapsychic mechanisms may be working here, we can conclude that dangers to a society lead to a psychological tendency to solidarity and strengthening of the political organization. This mechanism is highly functional because it makes the society better prepared to meet the crisis or external threats. We may see this as a kind of vicarious selection: Crises and external dangers cause a psychological armament, enabling the society to meet the dangers and possibly winning an intergroup conflict. The psychological armament by the threat of war causes the same cultural result as the war itself would: regularization - but faster and with fewer costs. This vicarious mechanism may have been created by either genetic or cultural evolution, or most likely by a combination of several selection mechanisms.

Imagine a society in surroundings where there is peace most of the time. A regal culture would be disadvantageous in times of peace because it would spend an unnecessary amount of resources on disciplining the population and maintaining an unnecessary warrior force, and also because cultural r-selection, just like genetic r-selection, entails an uncontrolled growth in population and hence exhaustion of natural resources. In a Malthusian way this may destabilize the ecological balance and lead to famine and mass extinction (Malthus [20]). On the other hand, cultural k-selection, like genetic K-selection, would stabilize the population and ensure maintenance of the means of subsistence.

A regal culture in a peaceful environment may be inexpedient, but a kalyptic culture in bellicose surroundings would be fatal. A kalyptic group will always be easy prey to the desire of a regal neighbor for expanding its territory. A group can only survive in hostile surroundings if it is regal. There is no need to limit the population - the frequent wars take care of that. On the contrary, a fast breeding population is necessary to maintain maximal military power.

The optimal solution for a group subjected to changing external influences must be *flexibility*. A fast regalization when an external danger is threatening, and fast return to a kalyptic strategy when the danger is over. The ability for fast adaptation can only be achieved by vicarious selection. You may regard this as feed-forward control. Any mechanism that leads to such an improvement in adaptability would have such a big fitness advantage, that it would be promoted by genetic as well as cultural selection. The gene/culture coevolution is estimated to have taken place through at least two million years (Durham [11]), which is more than sufficient for a mechanism like this to become fixated in our genetic and cultural heritage. The abovementioned mechanisms may be interpreted in this way, although this is admittedly not the only possible explanation for the observed psychological reactions.

8 Human History in Light of Cultural r/k-Selection

When humans began to cultivate the soil and raise cattle, they started a new evolution which has since influenced every aspect of human life. Previously, humans had lived as hunters and gatherers, but now different ways of living were invented. This invention was probably not selected for until an increased population density made it necessary to produce food in a more intensive manner than simply gathering the fruits of nature (Rosenberg [26]). Another possibility is that agriculture was first introduced on the demand of a powerful chief who wanted to create a basis for increasing the population of his chiefdom for strategic reasons.

The theory of regal selection plays an important role here. A war between two tribes may lead to the result that the strongest group conquers the weaker tribe and incorporates the latter under its command, so that the two tribes become united into one bigger society under a common leadership. The biggest groups - and those which are ruled by the most despotic chiefs - will be the strongest, and thus have the potential for growing even bigger. Through this selfperpetuating process, tribes and independent villages have been united into chiefdoms, chiefdoms have become states, states have become kingdoms, and finally, through an endless series of war and cruelty, enormous empires (Carneiro [8]). Agriculture has played an important role in this regal development because it has made possible an increased population density and hence a significant military superiority.

It is difficult to tell what initially set off this self-amplifying process of political integration. Is it agriculture which has given rise to a steep population growth, or is it overpopulation and famine that has necessitated the introduction of agriculture? Is it whimsical hostilities between chiefs of different tribes that has started a series of ever bigger wars and retaliations, or is it failing hunting luck that has forced a hungry population into war? Anthropologist Robert Carneiro thinks that the evolution towards ever bigger political units has started in places where small, very fertile, areas were surrounded by less attractive areas. The population has been concentrated on the most favorable areas, which made contests over the attractive territories very likely (Carneiro [7]).

The population density in infertile areas must necessarily be low, and the big distances makes war difficult or impossible. A kalyptic equilibrium may therefore be sustained in such sparsely populated regions for millennia, whereas there are ample possibilities for regal development in densely populated fertile areas. The border areas of a fertile territory particularly invite to conflict. Outside the fertile area live hunters or nomads who are attracted by the allure of the conspicuous prosperity of the agriculturalists. The peasants, in turn, are tempted by the immense, almost unused areas outside. The two groups may attempt to conquer each other's land, only to find that the captured land is unsuited for their way of life.

It is reasonable to assume that the spiral of ever increasing regality was started by an environmental factor, namely the proximity between two areas of very different fertility. The different ecologies of the two areas led to differences in way of life, political organization, and thus also a difference in social identity. The border between the two areas inevitably invited conflicts between the two quite different groups.

The concentration of the population in towns has made possible an increased specialization and division of labor, and hence the development of trade, crafts, technology, and finally industry. This development has introduced new parameters of competition in the cultural selection: food production technology, arms technology, and communication technology. Improved food production methods have enabled a more intensive utilization of natural resources and consequently a still higher population density. Improved weapons have led to military superiority. And improved means of transport and communication have made it possible to unite bigger areas under a common government.

This continued integration and regalization has taken place in Europe, Asia, and Northern Africa with few intermissions since the end of the Stone Age. But everything has a limit. In antiquity and the Middle Ages there was a limit to how big empires could be, and the limits were, first and foremost, set by the means of communication. It was difficult to control a war that took place many days' journey from the palace of the emperor, and it was difficult to motivate people to sacrifice big resources on a war that took place so far away that it seemed totally irrelevant.

When an empire has reached the limits to its growth, then regalization stops and kalyptization commences. Only a despotic government is able to keep together such a huge empire and maintain the necessary discipline and military strength. The population can hardly see the necessity of a highly tyrannical rule, so they start to rebel. When the emperor reluctantly begins to loosen his iron hand, then the internal conflicts start to flare up. The population suddenly appears to be far less homogeneous than previously believed. All those sub-groups which, one by

one, had been incorporated into the empire have preserved some of their religious or ethnic identity, and this identity is reinforced by their urge for independence and their rebellion against the despotism of the ruler. The population becomes divided and different sub-groups fight for independence. The empire starts to disintegrate and the monarch has a hard time trying to suppress the rebellious groups and keep his empire together. In the meantime, perhaps, a new kingdom nearby has started to grow. The old empire, which now has begun to disintegrate and kalypticize, is an easy victim to the expansive efforts of the new growing kingdom. The citizens do not wholeheartedly defend their country when attacked by the army of this new empire. They cannot imagine that the new ruler could possibly be more despotic and cruel than the old one, and many capitulate to the new emperor whom they regard as their liberator. In this way a new empire grows. Part of the old empire is incorporated into the new, and the rest is split up into smaller states.

History shows numerous examples of the rise and fall of mighty empires. For example, many historians have pondered over the fall of Rome, but seen in the light of the cultural r/k-theory, it is easy to explain. When an empire has reached the limits of its growth then kalyptization sets in and the empire is weakened. After a period of beginning kalyptization the realm is either conquered by a new empire or simply split up into smaller states. The recent breakdown of the Soviet empire is a proof that this history still repeats itself.

Cultural selection has been dominated by regalization since the Stone Age, reaching its zenith around the end of the nineteenth century. By then, all the continents had been colonized and further expansion possibilities were virtually exhausted. Now, lacking other possibilities, the great powers have begun to compete in conquering the outer space, but, since outer space is not habitable, this battle has only symbolic significance.

9 Regal and Kalyptic Cultural Products

The results of cultural r-selection is very evident in the area of religion. The most regal societies usually develop a monotheist religion with a powerful and punishing high god. Several meme theorists have demonstrated the suitability of religions for controlling a population (Lynch [19], Richerson & Boyd [25]), and monotheist and pantheist religions are particularly effective in this respect. The image of God as a supreme ruler is a psychological projection screen which legitimizes the undivided power of a monarch. In times of kalyptization, the god becomes imagined as more merciful, and the religion puts less emphasis on extreme punishments like purgatory and hellfire.

The regal characteristics of a society are also very conspicuous in its architecture. Powerful kings and religious leaders advertise their power by the building of ostentatious palaces, cathedrals, and monuments with the most costly and profuse ornamentation (Kempers [16]). This richness of ornamentation is repeated in painting, music, and other branches of art. The preferred music style of a culture has been found to be highly correlated with the social structure (Lomax [17]), and this correlation is particularly striking when we look at the regal/kalyptic characteristics of a society. Big orchestras and choirs led by a single conductor or master, producing highly embellished music, are characteristic of a regal culture, while kalyptic cultures prefer a music where accompaniment is equally important to the melodic voice, and where the musicians appear

to be equal (Fog [14]). The preferred styles of art, music, etc. are the ones which are psychologically most congruent with the social structure.

You may imagine different cultures, subcultures, and cultural products ordered on a continuous r/k-scale spanning from the extremely regal to the extremely kalyptic. Of course, such a scale has only intuitive value. It is hardly possible to assign absolute numbers since the r/k-value is not defined by one exact criterion, but evaluated by many different criteria, most of which are more or less subjective. The purpose of introducing such a scale is not to set culture on a mathematical formula, but to give meaning to comparative statements, such as: "*Rock music is more kalyptic than hymn singing*", and thereby provide a convenient classification scheme for cultures or cultural products. Of course, not all phenomena are comparable, but a necessary condition for a comparison to make sense is that you have a yardstick, and this is what I call the cultural r/k-scale. I have observed that many aspects of culture are connected to this cultural r/k-scale (Fog [14]), although no large scale statistics have been made yet. [Table 1] is a list of characteristics which I consider typical for regal and kalyptic cultures. The list is only intended as an aid to interpreting the r/k-scale. The reader is referred to (Fog [14]) for a more detailed discussion of how the r/k-dimension is reflected in different areas of culture.

	Regal	Kalyptic
Religion	Monotheism, ascetic, puritan.	Animism, polytheism, atheism, fertility cult, ancestor worship.
Philosophy	Individuals exist for the benefit of society. Ethnocentrism, racism, material growth, expansion.	Society exists for the benefit of the individual. Individualism, tolerance, human rights, protection of natural resources.
Politics	Powerful central government, imperialism, uniformity, intolerance, censorship, severe punishments, witch-hunts.	Decentralized government, democracy, tolerance, peace.
Art	Finical, perfectionist. Patterns with strict geometry. Perpetual repetition of small details. Portrays symbols of power such as gods, rulers, war heroes, or predators.	Unrestrained, improvised. Depicts pleasure, fantasy, colors, nature, animals, fertility, individualism, rebelliousness.
Music and singing	Monotonous, embellished, or by offensive regality pompous. Strict rules for rhymes and foot. Choir singing, litany. Praises gods, rulers, military superiority, true love.	Bass accompaniment dominates over melodic voice. Rhythmic, rhythm varied, imaginative, often improvised. Broad repertoire of text themes.
Dance	Organized, restrained.	Unorganized, hilarious.
Dress	Decent, tidy, uniform. Strongly sex-differentiated. Reflects social status.	Creative, individual, colorful, sexy. Reflects personal taste.
Architecture	Churches and government buildings are grandiose, ostentatious, rich in details, with oversized gates and towers.	Functionalistic, creative, individualistic, irregular. No stylistic demonstration of social differences.
Sexual behavior	Strict sexual morals. Stereotypical	Liberal sexual morals. Sex

	sex roles. Sex is only for procreation. Procreation is a duty. Children are regarded as asexual and ignorant. Contraception and abortion illegal. Early marriage. High population growth.	regarded as having several purposes. Flexible, individual, pleasurable behavior. Sexual education of children. Education comes before marriage. Contraception and abortion accepted. No population growth.
Occurrence	Mainland with many wars and cultural contrasts. Empires. New colonies.	Small isolated societies. Peaceful regions with low population density and no cultural contrasts.
Table 1. Typical characteristics of regal and kalyptic cultural products		

Generally, you should expect different aspects of a culture to be in reasonable agreement with regard to cultural r/k-status, but it is unlikely that you will find perfect agreement. A complex culture may have political fractions, subcultures and institutions with very different r/k-status. For example, there may be a rebellious subculture which supports more kalyptic values than the mother-culture and is aiming at influencing the mother-culture politically, or just creating space for an alternative life-style. You may also find religious sects which are more regal than their surrounding culture. Religious belief may be a more important part of personal identity than nationality to the sect members, and the regal activities mainly take the form of relentless efforts at gaining new proselytes. Other organizations may have the r/k-ideology which best suits their function, be it economic, military, correctional, or other institutions.

Another reason for lack of consonance between different aspects of a culture is simple inertia. Old art genres which fit the r/k-status that the society had several generations ago may be kept alive side by side with more modern genres. Magnificent old buildings are not torn down just because their architectural style is out of fashion.

10 Conclusion

The theory of cultural r/k-selection throws new light on important aspects of cultural life, including religion, ideology, art, etc. This new model has the potential for providing causal explanations to many cultural phenomena which hitherto have been difficult to explain and for suggesting causal connections between phenomena which previously have been regarded as independent. The attractiveness of this model lies in its usefulness for explaining historical developments as well as for predicting future changes, even when the knowledge of the selection mechanisms is incomplete.

The cultural r/k-theory resembles genetic r/k-theory in many ways, but it is definitely not a perfect analogy, and it should be regarded as a theory in its own right rather than an analogy. The cultural r/k-theory is only in its infancy. The possibilities of applying the methods discussed here to a diversity of cultural phenomena opens up a whole new range of topics for future research.

APPLYING MEMETICS TO FINANCIAL MARKETS: DO MARKETS EVOLVE TOWARDS EFFICIENCY?

By

Abstract

In the Finance literature, the concept of evolution has been applied loosely to justify assumptions of market efficiency. However, evolution has been invoked without applying any well-defined assumptions or rigorous analysis to determine if evolution would in fact lead to the stated results. This paper attempts to undertake that analysis and to bridge the gap between the fields of Finance and Memetics. This paper finds that most Finance literature inaccurately assumes that economic fitness would be the key variable in determining which memes prevail in the evolutionary process, when in actuality other dimensions of fitness are likely to prevail. Therefore, applying memetics to financial markets does not indicate that markets would evolve towards efficiency. In fact, evolution may actually lead to less efficient financial strategies prevailing.

Keywords: Memetics, Financial Market Efficiency, Market Evolution, Natural Selection

1 Introduction

In the field of Finance, much of the literature depends explicitly or implicitly on the concept of market efficiency. There has been extensive research on the subject of whether or not financial markets are in fact efficient; however, there has been very little thoughtful discussion as to the mechanism of this alleged market efficiency.

The theory of efficient economic markets in general and financial markets in particular actually predates the arguments for natural selection as an efficiency-generating mechanism. Market efficiency had been assumed at times as a simplifying generalization but more often it had been assumed to be an inevitable outcome based on a series of theoretical assumptions. These assumptions have included maximizing behavior both on the part of consumers (maximizing utility) and firms (maximizing profits), with actors having perfect information and no transaction costs, and other properties including non-satiation and transitivity of preferences. Working from these assumptions, economists have shown that markets will reach a state of efficiency (for example in [21] and [26]).

However, over time it has become increasingly evident that most if not all of the underlying assumptions of market efficiency are suspect. Actors do not have perfect information, there are transaction costs, and economic agents often do not act rationally even with the information they have (for example, managers often appear to "satisfice", or search for alternatives only when

performance falls below an aspiration level and only continue searching until a satisfactory option is found rather than finding best alternative [18, 24]). In addition, although maximizing of the expected value of outcomes is possible in a stochastic environment, when outcomes are uncertain, no expected value of returns can be formed, and therefore maximizing behavior is not technically possible. New evidence has been recently surfacing that stock market returns are chaotic [19] and therefore uncertain.

The argument for evolution in financial markets has come about partially to address criticisms of the underlying assumptions of market efficiency. If the original axioms behind efficient markets are not consistent with reality, then some other mechanism must exist if market efficiency is assumed to hold. Therefore, in the absence of any alternative mechanism, the theory of financial market efficiency relies on an evolutionary mechanism that is often-cited but usually stated only vaguely. Financial theorists assume that natural selection will favor strategies that are more rational and effective in investments, capital budgeting, and other financial decisions. This eventually leads to an efficient market, according to these theorists, since only the most effective strategies can survive in the marketplace.

Friedman [6] argued that irrational agents will disappear from the marketplace since they should systematically receive lower than average returns and higher than average losses. Miller [16] used the concept of evolution to reconcile the difference between financial theory and the actual decision procedures used by financial professionals within a corporation. According to Miller, "evolutionary mechanisms are at work to give survival value to those heuristics that are compatible with rational market equilibrium, however far from rational they may appear to be when examined up close and in isolation." Miller argues that it is not necessary that these efficient investors use highly sophisticated statistical and mathematical techniques to arrive at the efficient investment strategy. Evolution insures that only the heuristics with survival value will continue to exist. Zingales [28] might have stated the general position of modern financial theory best on this matter when he states "most economic theories are either implicitly or explicitly based on an evolutionary argument".

Keynes [14] offered an alternative theory for the behavior of financial markets. Keynes argued that with the development of financial markets, owners have become increasingly removed from the enterprises they hold a stake in. Therefore, "the element of real knowledge in the valuation of investment by those who own them or contemplate purchasing them has seriously declined." Keynes believes that in the absence of real knowledge, investors value financial assets based on a convention. That is, a belief that the existing state of affairs will continue indefinitely except to the extent that investors have specific reasons to believe otherwise. But this conventional valuation can become quite volatile since it has little foundation. As a consequence, "a conventional valuation which is established as the outcome of the mass psychology of a large number of ignorant individuals is liable to change violently as the result of a sudden fluctuation of opinion due to factors which do not really make much difference to the prospective yield; since there will be no strong roots of conviction to hold it steady." Keynes further argues that even experts in the market would do better by trying to understand these psychologically-based fluctuations than they would do by trying to understand the future real income streams of the underlying asset. Therefore financial markets become a place "where we devote our intelligences to anticipating what average opinion expect the average opinion to be."

This Keynesian psychologically-based model of financial markets probably explains most of the variance in market prices much better than prevailing efficient-market hypotheses. In fact, there is empirical support for the idea that market movements are not justifiable based on changes in the stream of subsequent dividends [23]. However, little attention has been given to the Keynesian viewpoint regarding financial market behavior. Probably, Friedman, Miller, or other traditional financial theorists would counter that even if this "convention" led in the short-term to irrational pricing, in the long-run selection pressures would again work to bring market pricing close to the value of the underlying asset. However, Keynes gives several valid arguments why the investor who looks at the long-term underlying value of assets will not dominate financial markets. First, it is easier to outguess the crowd than to guess long-term changes in real earnings.

As Keynes puts it; "Investment based on genuine long-term expectation is so difficult today as to be scarcely practicable. He who attempts it must surely lead much more laborious days and run greater risks than he who tries to guess better than the crowd how the crowd will behave." In addition, time is highly discounted by investors, so there is much more desire to make large gains quickly than to invest for the long-term. Furthermore, for investments made or answerable to committees, boards, or banks, strategies that are sensible long-term but that suffer short-term losses will not be tolerated. Haugen [9] discusses this last point in more detail. Modern markets are dominated by institutional investors. These institutional investors are evaluated for performance over relatively short horizons. Therefore, Haugen argues, investment market inefficiencies can persist even when the market knows about them if these inefficiencies can only be exploited over a long-term horizon.

Without the assumption of a natural selection process, there appears to be no compelling reason to assume financial markets would behave in a manner approaching efficiency in light of Keynesian arguments, empirical evidence of irrational market behavior, widespread use in the marketplace of flawed financial valuation techniques (according to traditional theory) and a wealth of psychological evidence of human biases in irrationality (for just a couple examples, see [1] or [20]).

Yet despite its widespread use in finance as an implicit mechanism for the assumption of market efficiency, the term evolution has been used in financial markets very loosely and without the analysis and scientific rigor to verify needed its validity. A good example from the field of Finance of the potential for inconsistencies in a loosely defined theory can be seen in Cox, Ingersoll & Ross [3]. The authors examine a very commonly used construct in the financial literature, the 'expectations theory' of the term structure of interest rates and find that this 'theory' is actually several independent and mutually incompatible concepts. A similar problem exists with the assumptions made in Finance regarding evolution. When examined closely, evolution in financial markets is complex and leads to results incompatible with the assumptions of financial theorists. By neglecting to examine this basic issue, the field of Finance has also failed to assimilate extensive literature that already exists in the field of evolution as it applies to human knowledge, or memetics.

Although the main arguments in this paper have not been presented before, some economists have attempted to demonstrate that natural selection will not lead to market efficiency. Hodgson [12] for example gives seven "Problems for Pangloss" (i.e., problems with the conclusion that

evolution always leads to the best possible outcomes). The problems he lists include (among others): the traits of new entrants affect the results, not just firm survival rates; evolution can be path-dependent and frequency-dependent; and there can be multiple, shifting adaptive peaks. Others presents different arguments against natural selection leading to behavior "as if" economic agents were optimizers include Nelson & Winter [17] and Heiner [10].

This paper will start out by assuming that there is an evolutionary process taking place in financial markets, particularly investment markets, and that the stable unit of evolution is the financial idea/strategy or meme. This paper will argue that these assumptions when thought through lead to conclusions inconsistent with the assumptions of financial theorists. First, it will be shown here that the economic reproduction (dollars producing more dollars) is a relatively slow and weak transmission method that will be dominated by interpersonal communication as a method of meme transmission. Then, if we add one additional assumption, that what gets communicated and assimilated most readily will at least sometimes differ from what is most economically viable (formally, economic fitness is not perfectly correlated from interpersonal fitness), this will lead to the conclusion that evolutionary competition will not lead to market efficiency in investment markets.

2 Applying Memetics to Financial Markets: Some Definitions

The theory of evolution was originally presented in Charles Darwin's the Origin of Species [4]. According to Darwin's theory, when there is variance in a population, the members of the population most fit to survive will have the most progeny and will therefore become more prominent in the population in future generations. Darwin called this process "natural selection". When there are new random variations continually added to a population, over many generations natural selection will lead to ongoing refinement of biological organisms and the spontaneous creation of new species. Darwin called this process "descent with modification". It was actually Herbert Spencer who popularized the term evolution for this process [12].

Dawkins [5] came up with the term meme as the smallest unit of cultural transmission, a concept parallel to that of the gene in biology. It is important to note that Dawkins' original discussion of the meme was in the context of a larger text supporting a perspective on genetic evolution that placed the gene at the center of the evolutionary stage rather than the species, group, or even the organism. Certain genes succeed, Dawkins argued, because they are successful at producing more identical genes. From this perspective, the gene can be viewed as "selfish" while the organism can be viewed as merely a vehicle for the genetic material. The same can be said of memes: the memes that succeed will be the ones best at producing more identical memes. On the surface, this appears to be a rather technical distinction between genes or memes and their host organism, but it can have important implications. For example, in biology it implies the sustainability of altruistic behavior towards kin, and it has important implications for the existence of sexual reproduction versus asexual reproduction [25] In financial markets, it implies that the memes that eventually dominate will be the ones most likely to reproduce themselves, which may not necessarily coincide with the memes that most successfully produce dollars. This point will be discussed in more detail in later sections.

In order for evolution to occur, we need to have

- A pattern of information,
- A way to generate variation in the pattern,
- A rationale for selecting variations that are adaptive, and
- A way of replicating and transmitting selected variations [7].

All four of these conditions are satisfied by investment strategies in financial markets, however there are actually two rationales for selecting variations that are adaptive (condition 3) and three methods for investment strategies to increase their presence in the marketplace, or replicate (condition 4). Examining the variations of conditions 3 and 4 are key to understanding how evolution will occur in financial markets since these variations leads to very different conclusions.

In financial and economic theory, the key basic unit of interest is the dollar. However, dollars cannot evolve because they lack in several conditions above, starting with the fact that they lack variation. Memes work as evolving units, but memes alone do not answer the questions that are of interest in finance. Financial theorists do not care if investing based on astrological signs becomes the favored method among randomly selected United States citizens, they only care about the prevalence of an investment strategy meme to the extent that there are dollars behind that strategy in the financial market. Therefore, we must take into account the dollars backing a certain investment strategy meme in the market since this will indicate the current prevalence of that meme in dictating market behavior.

To proceed then, we will define the evolving units, investment strategies, as falling within the larger category of memes. However, the states of nature that determine the efficiency of the market are defined in terms of dollar-weighted meme frequencies. Note that the dollar-weighted frequency of a meme is defined in terms of the dollars currently being invested using that meme. In other words, let us assume a specific investor has a million dollars of total investments, but that investor only invests a hundred thousand using a specific investment strategy. If we also assume that no other investor is using that strategy and that the total market is worth a hundred million dollars, that meme's current presence in the market place can be stated as having a frequency of 0.1%, not 1.0% which is the total investor's presence in the market place.

As mentioned earlier, the last two conditions required for evolution can now be seen to be satisfied in multiple ways. A financial theorist would define a meme's adaptive value or fitness based on its ability to reproduce more dollars for the individual holding the meme since investment strategies producing more dollars will tend to increase in dollar-weighted frequency in the marketplace. A memetic theorist would more likely focus on the meme's probability of interpersonal transmission when defining fitness, since the memes that are transferred from person to person more rapidly will tend to increase in dollar-weighted frequency in the marketplace. This suggests that investment strategy memes can increase dollar-weighted frequency either by reproducing dollars, or by transferring between people. There is actually one more leading to a total of three methods of replication:

- Economic Reproduction -- where the meme is not transferred interpersonally but the number of dollars associated with that meme increases through activity in the

marketplace (note that reproductive rates less than one would indicate a decline in dollars)

- Interpersonal Reproduction -- where a meme is transferred between individuals.
- Intrapersonal Transfer -- where a particular investor changes the frequency of a meme in the market by either shifting their personal investment strategy to favor one meme at the expense of another, or by changing their total investment presence in the financial market.

Only interpersonal reproduction represents true reproduction in the sense that only this method alters the frequency of the basic unit, the meme, in the human population. However, all three methods of reproduction can legitimately alter the dollar-weighted meme frequency in the market.

The concept of intrapersonal reproduction is somewhat more difficult than the other two, so some additional explanation is warranted. If an investor uses a certain financial meme to invest only part of his dollars in the market, the meme's dollar-weighted frequency can be defined in two ways: either by the number of dollars using that strategy or by the total dollars in the market by that investor. The former definition was chosen here. However, an investor can easily move funds around, increasing or decreasing the presence of a meme in the market. This does not require communication between people in any form, nor does it require that any profits are made in the market; therefore it technically is a third distinct type of reproduction. Intrapersonal reproduction is probably minor in impact, but is added here for completeness.

In reaching their conclusions regarding market efficiency, financial theorists have only taken economic reproduction into consideration. As the following sections will demonstrate, adding the other reproductive methods into the mix can lead to evolutionary outcomes quite different from the expectations of financial theorists.

3 Modeling the Evolution of Investment Strategy Memes

Although financial theorists have implicitly been assuming that economic reproduction is the dominant method of transmission of investment strategy memes, it should be noted that any reasonable model of financial markets must include interpersonal transmission. Without interpersonal transmission, the only way for a meme to reach dominance in the marketplace is for a single individual to dominate the marketplace. Of course, it is absurd to think of a single individual owning the majority of, for example, the United States stock market, and this is certainly not what Miller or other financial theorists are postulating when they discuss markets evolving towards efficiency.

It is also important to note here that a meme's interpersonal reproductive fitness may have nothing at all to do with its economic reproductive fitness. Although one could certainly argue that, for example, an investment strategy that works is more likely to be passed on interpersonally, the opposite viewpoint could also be argued as convincingly. Dawkins [5] described a meme's fitness in terms of its "psychological appeal". It can be argued that it is often

the theories with the least scientific validity that have the greatest psychological appeal. Scientifically valid ideas are often complicated, filled with nuances and caveats, and often lead to conclusions we would prefer not to believe. On the other hand, an appealing but scientifically inaccurate alternative meme can have many psychological advantages. It can be simple enough to remember and transfer easily, it can have intuitive appeal, and it can prevent cognitive dissonance by leading to conclusions that the investor would prefer to believe. An example of a psychological factor that can become important in investment strategy meme transmission is the psychological construct called 'perceived control' [20]. The finding of relevance here is that it may sometimes be psychologically healthy for people to believe they have control over a situation, even if the belief is illusory. The theory of financial market efficiency implies a relatively low level of control over financial markets by investors. Therefore, it is quite possible, for example, that theories implying markets that can be outguessed and profitably exploited using past market data may have more psychological appeal than an efficient view of financial markets.

One obvious example in financial markets is technical analysis, where investors attempt to guess future prices from past trends. With the exception of a few possible anomalies, there is considerable empirical evidence indicating that investment markets follow a random walk with future performance having no correlation with past performance (see [2, 13] for evidence regarding the stock market, and [27] for the earliest evidence regarding commodity markets). Yet this type of analysis continues to be performed not only by private investors but often by large investment firms that spend considerable amounts of money hiring 'experts' to guess what a stock's price will do tomorrow based on what the price did yesterday. Part of the reason might be the concept of perceived control mentioned earlier. There are also other psychological explanations. The idea that events known to be random can be somehow predicted from prior events is a common gambler's fallacy. There may be an inherent psychological tendency that makes humans prefer to see patterns in random events.

There are also institutional influences that will tend to encourage irrational beliefs. More specifically, it is in the interests of most industry professionals for investors to believe that simple schemes, strategies, and rules can be employed to outguess the market. Industry participants who make money by generating trades benefit when investors believe that they can outguess the market and therefore make frequent trades. Full-service investment firms and financial advisors gain when investors believe that their advice allows investors to outperform the market. Mutual funds benefit when investors believe that they will outperform the market. The investment industry has an interest in promoting certain strategies, even when evidence indicates that these strategies have no basis in reality. The end result is market volatility and inefficiency.

Also, it should be kept in mind that like its biological parallel, the market for memes can be highly competitive, with many potential contenders. If there are many possible competing financial memes and only a small percentage of those memes are economically sound, chances are that the most psychologically appealing memes are not the most economically sound memes assuming the two types of fitness exhibit some statistical independence.

The number of memes representing a given investment strategy in the population of humans (as opposed to dollars) at time $t+1$ can be defined as a product of its interpersonal reproductive fitness and the number of memes present at time t .

[NOTE: Equations not available]

The above equations only include the first two methods of reproduction and do not consider the rate of intrapersonal transfer. This has been done because it simplifies the analysis without reducing the validity of the conclusions. It is possible to expand and refine equations to more precisely model reality almost without limit. However, as the next section will demonstrate, the purpose here is to illustrate the simple point that economic fitness is not the primary driver of investment strategy dollar-weighted frequencies in the marketplace. Therefore, the equations have focused only on the two primary methods of transmission. Intrapersonal transfer, in any case, can only work to reduce the importance of economic fitness in the overall equation, since the initial investment strategies of new entrants into the marketplace, the strategies adopted by investors increasing their presence in the market, and switching between investment strategies will be driven by the same factors that determine interpersonal reproductive fitness rather than economic fitness.

4 Applying the Dollar-Meme Model using Real World Conditions

As equation 5 shows, there are many variables to consider in determining an investment strategy meme's total reproductive rate. Variables such as assimilation rates, retention rates, expression rates, and transmission rates each will follow their own rules for determining fitness which will have little or nothing to do with economic theory and a great deal to do with psychological theory. It should be noted that two of the interpersonal fitness terms, β and γ will always be less than or equal to 1 while α and δ can be much larger than 1. In fact, in this modern age of mass communication through television, books, the internet, and other mass media, the transmission rate can easily be in the millions and become the dominant variable in defining a meme's fitness. Even in the absence of the mass media and using reasonable assumptions, it can be demonstrated that interpersonal transmission will dominate economic transmission of dollar-memes. Let us take two people each with \$1,000 to invest. One uses a high return investment strategy that produces a constant rate of return of 30% while the other uses a low return strategy with a rate of return of only 5%. This would be considered a rather extreme difference in the financial world. Let us assume the low return strategy is somehow more appealing, and therefore led to 3 people with \$1,000 each to invest being told and assimilating/retaining the strategy within a year, while the high return gets transmitted to two people with \$1,000 to invest a year rather than three, then equation 1 shows the following reproductive rates:

- High profit dollar-meme:
- Low profit dollar-meme:

In this example, natural selection would eventually lead to the domination of the low profit dollar-meme, despite the fact that the economic fitness difference would be considered extreme. Although this is a somewhat arbitrary example, it is reasonable to expect that the interpersonal reproductive fitness will dominate in most real world circumstances. Economic Reproduction is

a relatively slow process. The 1.30 fitness shown above can be taken as an extremely high fitness for economic reproduction that is unlikely to be matched by even very fit strategies in the real world. Even each investor telling one other investor about a strategy at some time during the year (assuming the second investor assimilates and uses this information) leads to an interpersonal reproductive rate more than triple the economic reproductive rate. It is difficult to get precise interpersonal reproductive fitnesses for investment strategy memes, but there is clearly a potential for interpersonal reproduction to take place extremely rapidly relative to economic reproduction. Every year there are new books containing investment strategy memes that are transmitted to millions of people. Every day, investment television shows, radio shows, and print media speak to millions of people, and thousands of people receive calls from investment industry professionals. It is easy to imagine an investment strategy meme starting with a single individual and reproducing at a rate that reaches tens of thousands of investors within five years. This would imply an interpersonal reproductive rate of 6.0 or more, a rate that would make the economic fitness of a meme insignificant. In fact investment strategy memes must reproduce at very high rates at time, because entire new markets of futures and other financial instruments have developed and reached a critical mass within only a few years. These markets could not have developed so rapidly unless the memes guiding individuals to invest in these markets had not also reproduced equally rapidly.

It appears that under real-world conditions, the interpersonal fitness of a meme will dominate the economic fitness in determining the total fitness. In fact, using economic fitness alone, it is unlikely that much evolution of financial markets could have occurred due to time constraints since the environment changes more quickly than the natural selection process. Take, for example, one meme (A) that yields a return of 20% on average and another meme (B) that yields a return of 10%. If we assume that meme A is a new variation that initially exists in 1% of the population, we can determine how long it will take this new economically superior strategy to dominate 99% of the population. If we define the frequency of meme A as p , and the frequency of meme B as q , then, using an equation developed by Haldane [8]:

(6) [Equation Not Available]

where the 0 subscript represents the starting population frequency and the subscript e represents the ending population frequency, and the fitness, r , is defined as:

(7) [Equation Not Available]

or in this case:

This amount of time is older than most current financial markets. This is also much longer than the time it takes for the market environment to change dramatically. For example, the Capital Asset Pricing Model on which much of modern portfolio theory is based has only been in existence for about 35 years [15, 22] and the amount of time betas have been used extensively by investors as a measure of risk is much less than this. Therefore, it is unlikely that economic fitness alone would lead to an efficient natural selection process since the structure of the financial market changes more quickly than investment strategies change in frequency (i.e. using only economic fitness, by the time a successful meme becomes dominant, the environment for which it is successful no longer exists).

In addition to large scale structural changes in the market that occur over time, there are also cyclical effects to consider. For example, an investor who chooses stocks that move strongly with changes in the total market (a strategy of choosing high beta stocks) would do quite well in a period of rapid economic growth, while the opposite would be true in a recession. In general, the strategies that work best in bull markets are quite different than the strategies that work in bear markets. Besides the obvious general economic and market cycles, there are other cyclical changes in the environment that will affect investment strategy success including inflation rates, interest rates, the regulatory environment, and energy prices. Strategies that are the most successful in one environment will tend to reproduce rapidly at the expense of strategies that hold a moderate level of success but that work in all environments. These temporarily successful strategies may come to dominate the market only to meet with disaster when conditions change. The result will be inefficient and over reactive financial markets.

5 Summary and Conclusions

If we assume evolution takes place in financial markets and that the investment meme is the unit of selection, under real-world conditions, interpersonal reproduction will dominate economic reproduction as the primary reproductive method of investment strategy memes. Fitness and natural selection in financial markets will follow the theories and models developed in the field of Memetics rather than in Finance or Economics. If we further assume that economic and interpersonal fitnesses differ, the growth rate of an investment strategy meme may have little to no correlation with its economic soundness. This leads to a conclusion quite different from that previously assumed by financial theorists. Financial evolution will probably not lead to efficient markets and more likely would result in the dominance of inefficient market strategies.

Although financial markets and particularly investment markets have been used as the primary example in this article, the same assumptions regarding evolution and efficiency have often been made in general economic theory, and much of the discussion in this article would also apply to the field of Economics.

1. INTRODUCTION

In order for a pattern of information to evolve, we need a way of generating variations of the pattern, and a way of selectively replicating it. In *Adaptation in Natural and Artificial Systems* [11], Holland introduced a computational model of how these processes are carried out on patterns of genetic information in biological systems. In this paper we introduce a computational model of how they are carried out on patterns of cultural information in a society of interacting individuals.

Ideas, like genomes, are patterns that evolve; however their evolution is not subject to the same constraints, and employs different mechanisms. The generation of variation is less random in cultural evolution than in biological evolution; it reflects the accumulated knowledge of individuals, and the social structure in which they are embedded. In cultural evolution, selective replication is Lamarckian; an idea can be modified through experience after it has been phenotypically expressed. Genetic information is coded in a physical sequence of nucleotides, and contains the instructions for its own replication, whereas ideas are coded in patterns of neuron activation, and do not contain the instructions for their replication; they rely on human hosts to replicate them. Ideas that satisfy our needs or drives are preferentially learned and implemented. Thus the fitness landscape for the evolution of ideas is molded by our drives. By developing a minimal model that incorporates mechanisms which differentiate cultural evolution from biological evolution, we hope to broaden our understanding of how it is that something can evolve.

In *The Selfish Gene* [8], Dawkins coined the word "meme" to refer to "ideas, catch-phrases, clothes-fashions, ways of making pots or building arches." He elaborates: "Just as genes propagate themselves in the gene pool by leaping from body to body via sperm or eggs, so memes propagate themselves in the meme pool by leaping from brain to brain." Our model is called *Meme and Variations* because it is based on the premise that new ideas are variations of old ones; they result from tweaking or blending existing ideas [12]. We will explore the impact of three phenomena that are unique to cultural evolution. The first is knowledge-based operators: brains detect regularity and build schemas that they use to adapt the mental equivalents of mutation and recombination to their meme substrates. The second is imitation: ideas spread when members of a society observe and copy one another. This is seen in both animal and human societies [4, 15, 16]. Imitation enables individuals to share complete or partial solutions to the

problems they face. The third is mental simulation: individuals can imagine what would happen if a meme were implemented before resources are spent on it. This provides them with a rudimentary form of selection before the phenotypic expression of a meme.

We will adopt the terminology of biology. Each component of a meme is referred to as a locus, and alternative forms of a locus are referred to as alleles. The processes that generate variation -- the cultural counterparts to mutation and recombination -- are referred to as operators. Forward mutation is mutation away from the initial or wild type allele, and backmutation is mutation from an alternative form back to wild type. Changes in the relative frequencies of different alleles due to random sampling processes in a finite population are referred to as drift [17]. The set of all existing patterns is referred to as the population. Following Braitenberg [6], an individual is referred to as a vehicle, and the set of all vehicles is referred to as the society.

2. THE MODEL

2.1 THE DOMAIN

Donald [9] has provided substantial evidence that the earliest form of culture was mimetic display. The memes in Meme and Variations represent mating displays. A meme has six loci that correspond to six body parts: left forelimb, right forelimb, left hindlimb, right hindlimb, head, and tail. Each locus has a floating point activation between -0.5 and 0.5 which determines the amount of movement (angle of rotation from rest position) of the corresponding body part when the meme is implemented. A value of 0.0 corresponds to rest position; values above 0.0 correspond to upward movement, and values below 0.0 correspond to downward movement. Floating point loci activations produce graded limb movement. However for the purpose of mutation, loci are treated as if there are only three possible alleles at each locus: stationary, up, and down. Six loci with three possible alleles each gives a total of 729 possible memes.

2.2 THE NEURAL NETWORK

The neural network is an autoassociator; it learns the identity function between input and output patterns. It has six input/output units numbered 1 through 6, corresponding to the six body parts. It has six hidden units numbered 7 through 12, corresponding to the general concepts, "forelimbs", "hind limbs", "left", "right", "movement", and "symmetry" (Figure 1).

Figure 1 not available

Figure 1. The neural network. Arrows represent connections with positive weights. For clarity, negative connections are not shown. Connections to the symmetry unit are also not shown. Hidden units are linked with positive weights to input/output units that are positive instances of the concepts they represent, and linked with negative weights to input/output units that represent negative instances of the memes they represent (thus "left forelimb" is positively linked to "left" and negatively linked to "right"). Hidden units that represent opposite concepts have negative connections between them. The hidden units enable the network to encode the semantic structure of a meme, and their activations are used to bias the generation of variation (Section 2.5).

The neural network starts with small random weights between input/output nodes. Weights between hidden nodes, and weights between hidden nodes and input/output nodes, are fixed at +/- 1.0. Memes are learned by training for 50 iterations using the generalized delta rule with a sigmoid activation function [10]. The relevant variables are:

```

aj = activation of unit j
tj = the jth component of the target pattern (the external input)
wij = weight on line from unit i to unit j
b = 0.15
q = 0.5
aj = 1 / ( 1 + e-[ b sum wji ai+ q ] )

```

For the movement node, we use the absolute value of a_i . The error signal, d_j , is calculated as follows. For input/output units:

$$d_j = (t_j - a_j) a_j (1 - a_j)$$

For hidden units:

$$d_i = a_j (1 - a_j) \sum d_j w_{ij}$$

2.3 THE EMBODIMENT

The embodiment is a six-digit array that specifies the behavior of the six body parts. While the output of the neural network represents what the vehicle is thinking about, the embodiment represents what the vehicle is doing. A meme cannot be observed and imitated by other vehicles until has been copied from the neural network to the embodiment.

2.4 THE FITNESS FUNCTION

An optimal meme is one in which all body parts except the head are moving, and limb movement is symmetrical. (Thus if the left forelimb is moving up, the right forelimb is moving down, and vice versa.) This is implemented as follows:

```

F = fitness
c = 2.5
am = activation of movement hidden node
as = activation of symmetry hidden node
ah = activation of head node
i = } 1 if ah = 0.0; 0 otherwise
F = c am + 2 c as + c i

```

This fitness function corresponds to a relatively realistic display, but it also has some interesting properties. A vehicle that develops the general rule "movement improves fitness" risks overgeneralization since head stability contributes as much to fitness as movement at every other limb. This creates a situation that is the cultural analog of overdominance in genetics; the optimal value of this locus lies midway between the two extremes. We also have a situation analogous to bidirectional selection or underdominance; the optimal value of the tail locus lies at either of the two extremes. There is epistasis; the value of what one limb is doing depends on what its left-right counterpart is doing. Finally, since there is one optimal allele for the head, two optimal alleles for the tail, two optimal forelimb combinations, and two optimal hind limb combinations, we have a total of eight different optimal memes. This enables us to perform a comparative

analysis of diversity under different ratios of creation to imitation. Note that there are nonoptimal local maxima, corresponding to memes in which limbs are moving, but in the same direction.

2.5 THE MEMETIC ALGORITHM

The basic idea of the memetic algorithm is to translate knowledge acquired through the process of evaluating a new meme into educated guesses about what increases meme fitness. Each locus starts out with the allele for no movement, and with an equal probability of mutating to each of the other two alleles (the alleles for upward and downward movement). A new meme is not learned unless it is fitter than the currently-implemented meme, so we use the difference between these two memes to bias the direction of mutation. Two rules of thumb are used.

The first rule is: if the fitter meme codes for more movement, increase the probability of forward mutation and decrease the probability of back mutation. Do the opposite if the fitter meme codes for less movement. This rule of thumb is based on the assumption that movement can general (regardless of which particular body part is moving) can be beneficial or detrimental. This seems like a useful generalization since movement of any body part uses energy and increases the likelihood of being detected. It is implemented as follows:

```
am1 = activation of movement unit for currently-implemented meme
am2 = activation of movement unit for new meme
p(fmi) = probability of forward mutation at allele i (increased movement)
p(bmi) = probability of backward mutation at allele i (decreased movement)
```

```
IF (am2 > am1)
THEN p(fmi) = MAX(1.0, p(fmi) + 0.1)
ELSE IF (am2 < am1)
THEN p(fmi) = MIN(0.0, p(fmi) - 0.1)
p(bmi) = 1 - p(fmi)
```

The second rule of thumb biases the vehicle either toward or away from symmetrical limb movement. It has two parts. First, if in the fitter meme both members of one pair of limbs are moving either up or down, increase the probability that you will do the same with the other pair of limbs. Second, if in the fitter meme, one member of a pair of limbs is moving in one direction and its counterpart is moving in the opposite direction, increase the probability that you will do the same with the other pair of limbs. This generalization is also biologically useful, since many beneficial behaviors (walking, etcetera) entail movement of limbs in opposite directions, while others (galloping, etcetera) entail movement of limbs in the same direction. Space constraints do not permit a detailed explanation of the implementation of this rule; however, it is similar to the implementation of the first rule.

In summary, each meme is associated with a measure of its effectiveness, and generalizations about what seems to work and what does not are translated into guidelines that specify the behavior of the memetic algorithm.

3. PROTOCOL FOR EVOLVING MEMES

Vehicles are in a two-dimensional wrap-around 10x10 grid-cell world, one vehicle per cell. Each iteration, every vehicle has the opportunity to (1) acquire a new meme through creation or imitation, (2) update the mutation operator, and (3) implement the new meme.

Vehicles have an equal probability of creating and imitating. To create a new meme, the memetic algorithm is applied to the meme currently represented on the input/output layer of the neural network. For each locus, a vehicle decides whether mutation will take place. The probability of mutation is specified globally at the beginning of a run. If it decides to mutate, the direction of mutation is stochastically determined. If the new meme has a higher fitness than the currently-implemented meme, the vehicle learns and implements the new meme.

To acquire a meme through imitation, a vehicle randomly chooses one of its eight neighbors at random and evaluates the fitness of the meme the neighbor is implementing. If its own meme is fitter than that of the neighbor, it chooses another neighbor, until it has either observed all eight neighbors or found one with a fitter meme. If no fitter meme is found, the vehicle does nothing. Otherwise, the neighbors' meme is copied to the input/output layer of the vehicle's neural network, and learned.

Since in both creation and imitation a new meme is not acquired unless it is fitter than the currently-implemented meme, the new meme provides information that is used by the memetic algorithm. For example, since we arbitrarily chose a fitness function in which movement is generally beneficial, if the new meme codes for more movement than the old meme, the probability of forward mutation will almost always increase.

In the no mental simulation condition, whether the new meme was acquired through creation or imitation, it must be implemented for at least one iteration before its fitness can be assessed. In this case mutation operators are updated the following iteration.

The new meme is copied from the neural network to the embodiment. The vehicle is now implementing the new meme.

4. RESULTS

The following experiments were conducted using a mutation rate of 0.17 per locus, a 1:1 creation to imitation ratio, and all cultural evolution strategies operative, unless otherwise indicated.

4.1 OUTLINE OF A RUN

Initially all vehicles are immobile. The immobility meme quickly mutates to a new meme that codes for movement of a body part. The new meme has a higher fitness and is preferentially implemented. Diversity increases as memes continue to mutate and spread through imitation. Diversity peaks when the first maximally-fit meme is found, and decreases as the society converges on maximally-fit memes (Figure 2). Stabilization takes longer for epistatically-linked loci than over- or underdominant loci (Figure 3). The best performance is obtained with a high mutation rate: between 0.07 and 0.22 mutations per locus, or approximately one mutation per meme (Figure 4). This is probably because mental simulation ensures that poor memes are not

implemented, and good memes are imitated by others, so they are unlikely to be lost through mutation from the society as a whole.

Since we have eight optimal memes, there are many stable configurations for the distribution of memes. Drift is observed among equally-fit alleles (Figure 3), as predicted by Cavalli-Sforza and Feldman's mathematical model [7].

4.2 EXPERIMENTS

The three cultural evolution strategies -- mental simulation, imitation, and knowledge-based operators -- were made inoperative one at a time to determine their contribution to optimization speed and peak mean fitness. All three increase the rate of optimization, and mental simulation and imitation also increase peak mean fitness (Figures 5, 6, and 7).

The fitness of the fittest meme (Figure 8) increases as a function of the ratio of creation to imitation; however, the highest mean fitness is achieved when both creation and imitation are employed, in a ratio of approximately 2:1 (Figure 9). Since the vehicles with the fittest memes gain nothing by imitating others, there is a trade-off between average meme fitness and fitness of the fittest meme. Interestingly, meme diversity also varies with the ratio of creation to imitation (Figure 2), ranging from 1-2 memes when $p(\text{create}) = 0.25$ to 10-11 memes when $p(\text{create}) = 1.0$. When $p(\text{create}) = 0.75$, the society converges on 7-8 memes; it finds all (or nearly all) of the fittest memes. A nice balance is struck between the diversifying effect of mutation and the converging effect of imitation. In future experiments in which the fitness landscape will fluctuate, maintaining diversity may prove to be more important than speed.

5. FUTURE PLANS

This program will soon run on the connection machine, which will allow us to increase the size of the artificial society to several thousand individuals. We will examine the effect of erecting complete or semi permeable barriers between different societies, and the effect of migration.

A salient feature of human behavior is self-tuning; individuals modify their behavior according to how well it satisfies their needs or drives. Drives amount to conceptual niches that guide the evolution of culture. In future experiments vehicles will have two drives: to mate, and to acquire territory. The implementation of a meme will produce a response in neighboring vehicles that satisfies one drive or the other. When a drive is satisfied by implementing a display, its strength decreases. Fitness functions are not built into vehicles; they vary with the relative strengths of the drives. Memes are expected to specialize for one drive or the other; evolving along different trajectories toward two different basins of attraction.

Vehicles will be able to monitor their success with creation and imitation, and adjust their creation/imitation ratio accordingly. Individual differences will be introduced. Those that have a flawed memetic algorithm might specialize in imitation, while those that can not correctly translate the behavior of a neighbor into input to their neural network might specialize in creation. When vehicles can recognize one another and associate each other with the fitness of

their memes, a hierarchical social structure could emerge in which some vehicles are ignored while others are imitated by many.

Another plan is to add recombination: vehicles will acquire new memes by combining a meme that is being imitated with a previously-learned meme. This will allow them to specialize on different parts of a meme, and then share partial solutions. Vehicles will be able to monitor the relative effectiveness of mutation and recombination throughout a run, and adjust their frequencies accordingly.

6. COMPARISON WITH OTHER APPROACHES

This work differs from anthropological approaches to culture in that the goal is not to put together a detailed picture of how human culture evolved, but to abstract a general model of cultural evolution. Cavalli-Sforza and Feldman [7] have developed a mathematical theory of cultural evolution which has been extended by Lumsden and Wilson [14] and Boyd and Richerson [5]. The computational approach taken here allows us to model not only what happens, but the mechanisms that make it happen. It enables us to look for patterns that arise when these mechanisms are carried out in parallel in a society of interacting individuals, and to use relatively complex memes with more than one or two alleles.

Some interesting work has been done using a genetic algorithm to investigate the evolution of cooperation [2], and the interaction between genetic evolution, learning, and culture [3]. Ackley found that Lamarckian evolution increases the efficiency of a genetic algorithm [1]. Hutchins and Hazelhurst used a computer model to explore the relationship between environment, internal representation of the environment, and cultural artifacts that mediate the learning of environmental regularity [13]. These studies model vertical (intergenerational) transmission. Meme and Variations differs from these approaches in that we model horizontal (intra-generational) transmission, and we look at the dynamics that emerges when a society of agents can each invent their own ideas and imitate others.

ACKNOWLEDGEMENTS

I would like to thank Dave Chalmers and David Jefferson for useful comments on a draft of this manuscript, and Robert Boyd, Michael Dyer, and Charles Taylor for discussion. Thanks also to the Center for the Study of the Evolution and Origin of Life (CSEOL) at UCLA for inspiration and support.

To appear in *The Nature, Representation, and Evolution of Concepts*
(Ed. Philip van Loocke) 1997, Routledge Press.

1. CONCEPTUAL CHANGE: A SECOND FORM OF EVOLUTION

Knowing everything there is to know about how concepts or ideas can get represented in the mind of an individual would not take us far toward an account of why individuals understand the world the way they do, or explain why their understanding differs from that of their ancestors. While some ideas fade into obscurity, others rise to prominence and spread horizontally through society and vertically from one generation to another, getting progressively refined and embellished along the way. Ideas, like the strands of DNA that encode instructions for building and maintaining living organisms, seem to undergo a process analogous to biological evolution. Understanding this process is a vital part of unraveling our cognitive make-up.

There has been a slow but steady effort to map the concept of evolution onto the dynamics of culture. Popper [1963] and Campbell [1987] alerted us to the evolutionary flavor of epistemology. Dawkins [1976] introduced the notion of a meme--a replicator of cultural information analogous to the gene. In his words: "Just as genes propagate themselves in the gene pool by leaping from body to body via sperm or eggs, so do memes propagate themselves in the meme pool by leaping from brain to brain." Others have drawn from mathematical models of population genetics and epidemiology to model the spread of ideas [Cavalli-Sforza & Feldman 1981; Lumsden & Wilson 1981; Schuster & Sigmund 1983; Boyd & Richerson 1985; Hofbauer & Sigmund 1988].

These works point toward the possibility that memetics constitutes a second form of evolution, distinct from yet intertwined with biological evolution, with the potential to provide the kind of overarching framework for the social and cognitive sciences that the first form provides for the biological sciences. However, thus far memetics has not lived up to this potential, a situation that seems unfortunate given the success of the biological precedent. Although much was known about living things before Darwin, his theory of how life evolves through natural selection united previously disparate phenomena and paved the way for further biological inquiry.

Some believe that looking to biological evolution to gain insight into cultural evolution is a waste of time. As Gould [1991] put it: "Biological evolution is a bad analog for cultural change... biological evolution is powered by natural selection, cultural evolution by a different set of principles that I understand but dimly." However at an abstract level of analysis they amount to the same thing: exploration and transformation of an information space through

variation, selection, and replication. Both present the question of what underlying mechanisms could launch a self-perpetuating adaptive process. Thus the possibility that the two have enough in common that the former can pave the way for the latter seems at least worth pursuing.

Skeptics may wonder how we can develop a theory of cultural evolution before we understand how memes are instantiated in the brain. This situation has a precedent: Darwin came up with the theory of biological evolution through natural selection before the discovery of genes. It turned out that genes are laid out in a fairly straightforward way in physical space, which does not appear to be the case with memes. This does not mean they can't evolve, so long as there is a way of retrieving the components of a meme so they can work together as a unit. We may not yet know all the physiological details of how the information manifested in, say, a handshake between two individuals--with its unique arrangement of contact points, applied forces, and trajectory--can be traced back to these individuals' mental representations of handshakes, each other, and the situation they are in. But every day more pieces of the puzzle fall into place, and we will proceed with the confidence that the rest of the puzzle pieces exist and can be found.

This chapter outlines a theory of how memes evolve, and illustrates how the memetic perspective provides not only not only a foundation for research into the dynamics of concepts and artifacts at the societal level, but a synthetic framework for understanding how representations are generated, organized, stored, retrieved, and expressed at the level of the individual. It also sketches a tentative theory of how an infant develops a sustained train of thought and thus becomes a cog in the meme-evolving machinery.

Implications of this theory pertaining to the mechanisms underlying creativity, and why it is virtually nonexistent in other species, are explored. It concludes with discussion of how a cultural-evolution perspective can shape and inspire research in the cognitive and social sciences.

1.1 COMPONENTS OF AN EVOLUTIONARY SYSTEM

In order for evolution to happen there must be:

1. A pattern of information (a state within a space of possible states).
2. A way to generate variations of the pattern (explore or transform the space).
3. A rationale for selecting variations that are adaptive-- tend to give better performance than their predecessors in the context of some problem or set of constraints (a fitness landscape applied to the space).
4. A way of replicating and transmitting (or amplifying, as molecular biologists refer to it) the selected variations.

In biological evolution, the evolving patterns of information are genes encoded as sequences of nucleotides. Variations arise through mutation and recombination, and natural selection weeds out those that are maladaptive. Replication takes place at the level of the genotype. In cultural evolution, the evolving patterns of information are memes--mental representations of ideas,

behaviors, or other theoretical or imagined constructs, perhaps encoded as patterns of neuron activation. Variation arises when representations are combined, transformed, or reorganized. Replication is phenotypically mediated; it occurs when representations are transformed into action or language, transmitted through processes such as imitation, and reproduced, more or less, in another brain. Incorporation of these new information patterns into the society alters the selective pressures and constraints exerted by the social environment, which in turn leads to the generation of yet more patterns. Thus memes, like DNA, comprise a self-sustained system for the relentless exploration and transformation of a space of possible patterns.

1.2 COGNITION IS NOT JUST A PREDICTABLE EXTENSION OF BIOLOGICAL EVOLUTION

The line of reasoning presented here can be succinctly conveyed in terms of information, which is related to the number of differences required to specify the state of a system [Shannon & Weaver 1963; Bateson 1972]. States have not only a structure of difference relations between them, but also a combinatorial structure--each state can itself comprise an information space--so that complex information can be built up from simple information. We can rate each state in a space of possible states against some performance measure or fitness criterion and the result is referred to as a fitness landscape, and we can move from one state to another by way of a computation. The world can be viewed as a vast network of computations wherein information is created, transformed, and destroyed. This information often exhibits pattern, or statistical regularity that can be expressed mathematically.

After seeing many shadows cast by the same object, we can develop an internal model of what that object looks like without having seen it. If more than one object is casting shadows we can learn to tell which object is casting any particular shadow.

Similarly, by viewing every pattern we encounter as a shadow or footprint of one or more broad causal principles [note 1], we can gain insight into the causal principles that manifest pattern.

If you were to go back to sometime during the first billion years of Earth's history, the only causal principle you would need to invoke to explain pattern in the information present (with the exception of yourself) would be the physical constraints and self-organizing properties of matter.

If you were to go back to sometime after the origin of life, approximately three billion years ago, this would no longer be the case. Not that life doesn't exhibit the properties of matter. But it would be virtually impossible for, say, a giraffe to appear in an information space not acted upon by natural selection. Another causal principle--biological evolution--would have to be invoked from this point on.

Today the Earth is embedded with artifacts like computer networks and circuses that cannot be accounted for by appeal to either the properties of matter or biological evolution. That is, biological evolution does not provide us with adequate explanatory power to account for the existence of computers any more than the properties of matter can explain the existence of giraffes. Computers are manifestations of yet another causal principle: the evolution of culture.

Thus pattern in the structure and dynamics of information we encounter in the everyday world can be traced to three broad causal principles the physical constraints and self-organizing properties of matter, biological evolution, and cultural evolution. This classification scheme, like all classification schemes, is somewhat arbitrary. There may be subclasses of these principles that deserve to be considered principles unto themselves [note 2], or one could argue that evolution is a self-organizing property of matter, albeit a spectacular one [note 3]. The point is: culture is the only process that has arisen since the origin of life that relentlessly exploits the combinatorial potential of information. Despite the fact that culture is grounded in biology (like biology is grounded in the physical constraints and self-organizing properties of matter), the probability of computers arising spontaneously in an information space not acted upon by cultural evolution (like the probability of giraffes arising spontaneously in an information space not acted upon by biological evolution) is vanishingly small. Thus it is inappropriate to dismiss culture as a predictable extension of biological evolution. It is different from anything else biology has produced.

Since the machinery that renders cultural evolution—the human brain—is a product of biological evolution, much of what is 'out there' cannot be cleanly traced to a biological or cultural origin. We will discuss how biology constrains culture through the preferential spread of memes that satisfy biologically-derived needs. It goes the other way too; culture not only affects biological fitness through its effect on behavior (a phenomenon known as the Baldwin Effect) but it dramatically modifies the biological world. Some of the ways in which biological information gets tainted with cultural information seem relatively inconsequential, such as the trimming of hedges, whereas others, such as dog-breeding, have a long-lasting effect. (In fact, one could view dogs as the consequence of a memetic trajectory that was launched by the need to protect property.) Nevertheless, much as it is not imperative to address the role of physical constraints like gravity in studies of, say, embryonic development or squirrel foraging behavior, much can be said about culture without addressing the role of biological constraints.

1.3 TAKING THE MEME-EVOLVING APPARATUS SERIOUSLY

The most salient shortcoming of existing models of cultural evolution, and quite possibly the reason they have had relatively little impact, is that although they tell us much about the transmission or characteristics of 'catchy' memes, they fail to adequately address the issue of how novelty is generated. To be of significant theoretical or predictive value, memetics must give serious consideration to the processes by which experience in the world turns into new memes in our brains, and address how memetic novelty is expanded further through creative processes.

Studies of creativity, on the other hand, suffer from the opposite problem. They tend to focus on the individual, obscuring the fact that creativity is a collective affair [e.g. Lenat 1974; Schank & Leake 1989; Mitchell 1993; Boden 1991]. The ideas and inventions an individual produces build on the ideas and inventions of others. Which memes spread and which ones die off reflects the dynamics of the entire society of individuals hosting them.

Although at a sufficiently abstract level the notion that culture evolves is obvious, we lack a theoretical framework that bridges transmission studies with studies of creativity, and spells out explicitly how the concept of evolution maps on to the case of culture. To accomplish this we

need more than a quick and dirty list of what makes a meme catchy; we have to consider the extent to which it resonates with and enriches the complex web of assumptions, beliefs, motives, and attitudes of its host--no simple matter. In short, we have to take the meme-evolving apparatus very seriously.

2. MEME: INFORMATION UNIT THAT EVOLVES THROUGH CULTURE

Because the concept of the individual is so germane to the human experience we have an anthropocentric tendency to assume that the individual is the appropriate basic unit of analysis. This tendency is probably exacerbated by the fact that in biology the individual is the object of the relevant evolutionary process (or more specifically the phenotypic expression of the information undergoing evolution). The memetic approach involves relinquishing our focus on the individual and concentrating instead on the meme as the object of a second evolutionary process that makes cognition possible. This perspective can feel unnatural and disorienting but it discloses population-level phenomena that would otherwise go unnoticed because they are not readily detected through introspection.

2.1 DISTINCTION BETWEEN A MEME AND ITS PHENOTYPIC IMPLEMENTATION

Durham [1991] defines a meme as "any kind, amount, and configuration of information in culture that shows both variation and coherent transmission." Problems with this definition arise because it does not distinguish between cultural information as mental representation and cultural information as implemented behavior or artifact.

The genotype-phenotype distinction is useful here. The cultural analog of a genotype is the mental representation of a meme, and the analog of a phenotype is its implementation, or the form it takes if it gets expressed or communicated, typically as action or vocalization. Implementation transforms a meme, incorporating syntactic features characteristic of the channel through which it is conveyed [Brooks 1986]. Thus, for example, a dance step looks different with each individual who performs it.

2.2 INTRA-MEME STRUCTURE: CORE, ENABLER, AND HITCHHIKER FEATURES

Biologists use the term *allele* to capture the notion of alternative heritable versions of a gene, and Durham [1991] accordingly adopted the term *TallomemeU* to refer to alternative versions of a meme. This basic concept was tailored to meet the constraints of biology; we all have the same number of genes, and two alleles of each gene (one from each parent). The cultural analog may be too clumsy to capture the subtle relationships between memes. Memes often appear to be stored in a distributed, network-like fashion, connected through webs of association [Hebb 1949; Quillian 1968; Pribram 1974]; there is not necessarily a definitive rationale for saying where one stops and another begins, in semantic space let alone physical space. For example would we consider 'My mother looks good in blue' and 'My mother looks good under a blue umbrella' to be allomemes of the same meme, or different memes?

This kind of difficulty is circumvented by avoiding the notion of alternate versions altogether and using the term feature to refer to a component of a meme. Thus related memes share features. In this paper, feature can refer to a component with any degree of granularity below that of the meme in question; thus the scope of what might be considered a feature could range from an entire array of visual information depicting every perceived quality of a particular umbrella (such as might occur early on in perception) to one bit of information indicating the presence or absence of an umbrella (such as might occur at an advanced stage of cognitive processing). There can be nonlinear (epistatic) relations amongst the features of a meme, as well as between a meme and its implementation.

A first step toward a science of memetics is to decompose memes into features or feature schemata according to how they relate to fitness. Here we will distinguish the following categories: (1) core features that contribute directly to the fitness of a meme, (2) enabler features, that enable or facilitate the implementation of core features, and (3) hitchhiker features, which exist in the meme due to arbitrary or accidental historical associations with features of the first two kinds. Core features tend to convey semantic information, and enabler features syntactic information, though one can think of situations in which some semantic information serves simply to facilitate expression of other semantic information i.e. functions as an enabler. The first two categories are vaguely analogous to the categorization of genes as structural or regulatory, and the last category is inspired by the phenomenon of genetic hitchhiking [Kojima & Schaeffer 1967; Maynard Smith & Haigh 1974; Kaplan, Hudson, & Langley 1989]. The closer together genes are on a chromosome the less likely they will be separated by crossover, so the more tightly linked they are said to be. Hitchhiker alleles confer no fitness advantage, but endure because they are linked to alleles that are important for survival. In both genetic hitchhiking and its cultural analog there is indirect selection for useless (or even detrimental) patterns through their association with beneficial ones. The concept of hitchhiking is closely related to that of exaptation -- the evolution of organs or traits not evolved through natural selection for their current use [Gould 1982].

2.3 MEME AS AN EXPERIENCE ENCODED IN THE FOCUS

In his book *Thought Contagion*, Aaron Lynch claims "Much as computer viruses make up a small fraction of computer software, so too do pernicious thought contagions form a small part of our mental software." But is this conservative approach necessary, or even sensible? Where do you draw the line between potentially culturally-transmittable memes and the rest our "mental software"? The haiku-writer, for example, seems able to draw upon any sort of thought, memory, or imaginary construct.

Here we will explore the opposite approach to that taken by Lynch; we bite the bullet and consider anything that can be the subject of an instant of experience, to be a meme. The category meme now includes not only obviously transmittable ideas like 'Be good or you will go to Hell', but everything from a particular experience of vibrant redness, to a realization of a shorter route to work, to a feeling of elation associated with a friend's facial expression or posture. This may strike some readers as outrageous, but it doesn't really make things as unwieldy as it might seem to at first glance. For the price of this added complication we gain a bridge that connects memetics with phenomena like perception, body language, planning, deductive reasoning,

emotion, categorization, analogy... the stuff of the social and cognitive sciences. It may be our only viable direction. A theory of mind that can account for myth and freestyle dance, not to mention rapid personality assessment, is not easily achieved.

Our concept of meme is made more manageable by invoking Kanerva's [1988] notion of the focus--that part of the mind in which sensation (either external or internal e.g. hunger) and stored memory interact to produce a stream of experience. The states of the neurons that comprise the focus determine the content and experiential quality of an individual's awareness. One can think of a meme as a pattern of information that is or has been encoded in an individual's focus. It can be subjectively experienced as a sensation, idea, attitude, emotion, or combination of these, and it can direct implementation by the motor apparatus.

3. THE MEME-EVOLVING APPARATUS: CONCEPTUAL NETWORKS

Memes are woven together in an internal model of the world or worldview, which their host calls upon to figure out what to do whenever a situation is too complicated for its hardwired instincts. The worldview orchestrates behavior such that a meme gets implemented right when it is likely to be useful, and that increases the probability that other hosts will consider it worthy of replication. This section briefly discusses some ideas about how the worldview is structured.

3.1 REPRESENTATION OF LOGICAL RELATIONSHIPS

A worldview with enough internal consistency to put together strategies and solve problems must have a way of representing not only memes themselves but the logical relationships amongst them. McCulloch and Pitts [1943] showed that networks made of neuron-like components that perform the logical operations AND, OR, and NOT are theoretically capable of computing any Turing machine-computable function. In connectionist-type systems, logical relations are represented implicitly as constraints on the possible states of a system, and computation proceeds through settling into a solution that satisfies many constraints, rather than then explicitly calculating a solution. This is accomplished through modification of the associative strengths amongst the components of the system, and the process is referred to as relaxation or simulated annealing.

3.2 THE BABY AND THE BATHWATER: CONCEPTUAL LINKAGE DISEQUILIBRIUM

Arguments against a theory of cultural evolution generally consist of a series of statements as to how the cultural situation differs from that of biology [e.g. Gould 1991; Thagard 1980]. These arguments, however, do not constitute a viable reason to discard the idea that culture is an evolutionary process. Imagine that 100 years before Darwin proposed the theory of biological evolution through natural selection, another scientist had discovered another system whereby information patterns evolved, say in a test tube. Given this scenario, would it have made sense for Darwin to dismiss biological evolution simply because it works differently from the test tube form? This would obviously have been foolish. It would have robbed humanity of not only the unifying power of a theory of biological evolution, but the opportunity to use knowledge of how evolution works under one set of constraints and affordances as a scaffold to direct the study of

how it works under different constraints and affordances. But time and again it is argued that a theory of cultural evolution is doomed simply because it would have to work through different mechanisms from those of biological evolution.

Ironically this situation in itself provides us with a nice example of how knowledge of evolution acquired in the realm of biology can help unravel analogous situations in the realm of culture. The biasing effect of historical association is an important theme in population genetics. Alleles of linked genes, such as those that code for red hair and freckles, continue to co-occur more often than chance even after individuals in the lineage from which these alleles originated begin mating randomly with individuals from other lineages that did not have these alleles. One can theoretically measure the number of generations necessary for these genes to achieve a state of random association or linkage equilibrium, and this process can be modeled computationally. Similarly, people often have difficulty applying an idea or problem-solving technique to situations other than the one in which it was originally encountered, and conversely, exposure to one problem-solving technique interferes with the ability to solve a problem using another technique [e.g. Luchins 1942]. Psychologists refer to this as mental set (though it is more commonly known as 'throwing the baby out with the bathwater'). We could view mental set as a state of conceptual linkage disequilibrium. In the present example, conceptual linkage disequilibrium hinders our ability to abstract the basic concept of evolution from its biological manifestation so that it can be applied with ease to the case of culture. One could argue that it would make sense for cultural evolution to be the default form of evolution in disciplines outside of biology, much as in tropical climates the default form of skiing is water-skiing rather than snow-skiing.

Conceptual linkage equilibrium is achieved when all instances of hitchhiking have been obliterated. In an influential paper on the relationship between DNA polymorphism and recombination rates, Begun and Aquadro [1992] suggested that genetic hitchhiking may have significant evolutionary impact:

This correlation suggests that levels of neutral variation in many of the gene regions for which variation has been measured have been reduced by one or more hitchhiking events. Provided that a new selectively favored mutation goes to fixation before another advantageous mutation arises close to it, each fixation will be surrounded by a 'window' of reduced polymorphism, the relative size of which is proportional to the rate of recombination for that region of the genome.

The general idea here translates nicely to cognition: if a meme goes to fixation in a society due to selective advantage conferred by one or more core features, its enabler and hitchhiker features will also exhibit reduced polymorphism, and the size of the window will vary with the extent to which hitchhiker features are conceptually bound to that meme. (For example, the basic concept of a typewriter/computer keyboard was historically enabled by the QWERTY keyboard design, which has now gone to fixation despite poor performance relative to other possible keyboard designs.)

3.3 INDIVIDUAL VERSUS SOCIETAL WORLDVIEWS

Our worldviews overlap to the extent that similar experiences and genetic make-ups cause our brains to store the same memes and styles of computation. But they don't overlap perfectly. Each host's train of thought traces out a unique trajectory through conceptual space. It can be useful to think in terms of not only the worldview of an individual, but also the worldview of a group or even human society at large, wherein all frontiers of human endeavor are incorporated.

4. SELECTION AND MEME FITNESS

The next few sections examine in some detail how each of the three phases of evolution--selection, variation, and transmission--map onto the case of culture. Though these phases are discussed one at a time, it is worthwhile to keep in mind that in culture they are less spatiotemporally distinct than in biology. Selection can be coupled to either the generation of variation, or replication, or all three can occur simultaneously (for example when paraphrasing).

4.1 MEMES RELY ON BRAINS TO SELECT, VARY AND REPLICATE THEM

Von Neumann [1966] postulated that any self-replicating system consists of two parts: (1) uninterpreted information—a self-description that is passively copied to offspring and (2) interpreted information instructions for how to construct offspring. This turned out to be true of the genetic code; there are genes that provide instructions to the body for how to sustain itself, and genes that provide instructions for how, with the help of someone of the opposite sex, to create a child. But unlike genes, memes do not come prepackaged with instructions for their reproduction. They rely on the pattern-evolving machinery of their hosts' brains to create, select, and replicate them. Since we preferentially spread ideas that satisfy needs, our needs define viable niches for memes to evolve toward. As infants we might cry and kick no matter what need is most pressing, but as children we acquire and continually refine a repertoire of memes that, when implemented, satisfy various needs. We learn that reaching into the cookie jar satisfies one need, shouting help satisfies another, et cetera. Our memes, and the behavior they elicit, slide into need-defined attractors (regions of stability) in the memetic fitness landscape.

The fact that memes are not independently self-replicating does not prevent them from achieving reproductive success. In fact it may ironically work in their favor, because the cognitive machinery they depend upon not only (1) organizes them into a worldview which orchestrates their implementation in a way that makes their usefulness apparent, but (2) transforms them to produce 'offspring-memes'. Both tendencies--to reorganize memes, and create new ones--stem from the need to be able to evaluate and carry out plans of action, and seem to resurface when needs more directly relevant to survival have been met. We now turn to how these more pressing survival needs affect meme evolution.

4.2 BRAINS SELECT MEMES THAT SATISFY BIOLOGICAL AND CULTURAL NEEDS

Since many of our needs have a biological basis--e.g. the need for food, shelter, et cetera--meme generation is largely constrained by our heritage as products of biological evolution. Thus the topology of the memetic fitness landscape largely echoes that of the biological fitness landscape. In the short term, the biological fitness landscape, and thus the memetic fitness landscape, fluctuates continuously as one need is satisfied and others take precedence [Hull 1943; McFarland & Sibly 1975; Gabora & Colgan 1988; Maes 1991]. For example, after eating, ideas that pertain to finding food are less likely. However over the lifetime of an individual the set of biologically-based needs remains relatively constant. The trajectory of survival-motivated thought can be described as a limit cycle (periodic attractor) that moves through the set of stable memes whose implementations satisfy the various biological needs.

Variation-inducing operations (which will be discussed in the next section) restructure conceptual space and thus affect the memetic fitness landscape. Much as the evolution of rabbits created ecological niches for species that eat them and parasitize them, the invention of cars created cultural niches for gas stations, seat belts, and garage door openers. As one progresses from infancy to maturity, and simple needs give way to increasingly complex needs, the stream of thought acquires the properties of a chaotic or strange attractor, which can be viewed as the formation of crevices in the original limit cycle. The landscape is fractal (i.e. there is statistical similarity under change of scale) in that the satisfaction of one need creates other needs every crevice when examined closely reveals more crevices. This is analogous to the fractal distributions of species and vegetation patterns described by ecologists [Mandelbrot 1982; Palmer 1992; Scheuring & Riedi 1994]. An endpoint of a cultural evolution trajectory turns out to be not just a point in multidimensional space, but a set of points with their own fitness metric--a micro-landscape in its own right. So although the memetic fitness landscape loosely follows the biological fitness landscape, there are places where it deviates, and this effect undoubtedly becomes more pronounced throughout an individual's lifetime. This means that the potential for meme diversity is open-ended. Fueled by need and constrained by association we carve out trajectories through meme space, and because the fitness landscape that guides this process is fractal, every time that landscape steers the production of a new meme (or even just a slight variant of a preceding meme), the new meme in turn redefines the landscape, and so on, recursively. Thus there is a continuous co-evolutionary interplay between meme and landscape, and this would seem to contribute to the oft-noted rapidity with which culture evolves.

4.3 HARD-WIRED SELECTION

To the extent that the memetic fitness landscape echoes the shape of the biological fitness landscape, to which we have been adapting since life began, cultural selection is built right into our architecture. Our perceptual and cognitive systems are wired up such that they are primed to focus on and highlight those aspects of external reality that are relevant to our survival (or were in the past). The mental representations we form reflect that bias [e.g. Hubel & Wiesel 1979; Marr 1982].

Second, the associative organization of memory both permits and constrains meme storage and variation- generating operations. This is discussed in detail extensively elsewhere [e.g. Van Loocke 1991 and this volume] and will not be addressed here.

4.4 MALLEABLE FORMS OF SELECTION

In order to create, or even just understand, a new meme, there has to be a conceptual framework from within which it will make sense, and a need, or niche, for it. Therefore, any relevant precursor or proto-memes must first be assimilated [Wallas 1926]. This constraint amounts to a malleable, or plastic, form of selection on new memes.

When one host exhibits a meme that another observing host values, the observing host often displays reinforcing body language and emits words of encouragement. Likewise, if the meme is threatening or inconsistent with valued memes, the observing host's words and behavior tend to be discouraging. Our need for social acceptance makes us more likely to exhibit memes that have been reinforced and less likely to exhibit those that have been discouraged. From a meme's-eye perspective this looks like a subtle strategy whereby a meme acting through one host selectively shapes the probability of its implementation in other hosts.

Selection can also occur after a representation has been internalized but prior to being phenotypically expressed. For example, mentally &simulating what would happen if an idea were implemented can weed out unworthy ideas [Nersessian 1993]. The success of mental simulation varies with the accuracy of one's' internalized model of the world, but it provides at least a rudimentary form of selection.

Finally, selection can operate through biased transmission; that is we choose to imitate certain individuals and not others [Boyd & Richerson 1985].

5. CREATIVITY: WELLSPRING OF CULTURAL VARIATION

5.1 STRATEGY GUIDES TRAJECTORIES THROUGH MEMETIC FITNESS LANDSCAPE

The existence of an open niche does not guarantee that the niche will ever be found. In biology the process by which this happens is largely random. Though most mutations and recombinations are detrimental, so many variants are generated that it is not necessary to be clever about how they are generated. We could say that biological evolution is a more breadth-first search algorithm than cultural evolution because it relies primarily on massive parallelism rather than strategy.

In culture, on the other hand, variants are generated strategically. We could say that cultural evolution is a more depth-first approach to searching a space of possibilities. The trajectory of a stream of thought is constrained by connections between representations that are similar or spatiotemporally related [Schank 1983], which increases the probability that an advantageous variant is found. For example, when considering the problem of having to get out of your car every day to open the garage door, you would not think about doilies or existentialism, but

concepts related to the problem electricity, human laziness, and various openers you have encountered before. If you were to spend several months on this problem, ideas that pertain to openers of various kinds would for you become a highly active region of conceptual space, analogous to the uncharacteristically high level of activity (and polymorphism) in a small portion of the human genome known as the major histocompatibility complex (MHC) which deals with immune response [Hughes & Nei 1988].

5.2 WORLDVIEW REORGANIZATION: CHUNKING, CATEGORIZING, AND REDESCRIBING

Frequently many memes get integrated into one through a process referred to in the psychological literature as chunking [Miller 1956]. Chunking involves forming associations amongst previously-learned memes and establishing this constellation of associations as a new meme in long term memory; it is analogous to the formation of co-adapted genes, or schemata [Holland 1975].

Whereas chunking generally refers to the binding of semantically unrelated memes (as in the memorization of an arbitrary string of numbers), categorization involves the recognition of semantic relationships. Categorization and the resultant hierarchical structure of knowledge is discussed in other chapters and will not be addressed here in any depth, though it is of relevance to point out that it seems reasonable to expect that the more extensively memes have been chunked or categorized, the greater the complexity of what can be held in the focus at once. Thus what constitutes a meme (and thus a feature) will differ amongst individuals and within an individual over time.

During creative thought, memes potentially relevant to a solution would evoke or activate one another, altering or strategically (though not necessarily consciously) manipulating them, a process that is said to involve pattern completion, constraint satisfaction [Rumelhart & McClelland 1986], and the tweaking, blending, redescription, abstraction, and recoding of representations [Hofstadter 1985; Holland et al. 1986; Karmiloff-Smith 1986; 1992; Ram 1993; Clark & Thornton 1995]. Neurophysiological evidence suggests that creating new contexts for representations, that is manipulating them, involves hippocampal binding or linking [Squire 1992], and synchronization [Klimesch 1995], of features encoded by distributed cortical cell assemblies.

One could argue that recreation is the re-creation of information patterns in different domains from the ones in which they were originally encountered, thereby filtering out conceptual prejudices that reflect nothing more than mechanical constraints or historical legacies of the original domain. Play, intellectual pursuits, and other creative endeavors are then algorithms for achieving a state of conceptual linkage equilibrium through mental operations that, like genetic recombination, increase polymorphism by reducing fixation through hitchhiking.

5.3 SPARSE DISTRIBUTED MEMORY AS A PLATFORM FOR GENERATING NOVELTY

If the worldview is like a patchwork quilt of memes, thought is like shining a flashlight onto the quilt such that the light is not restricted to one patch but can overlap several, distilling what is relevant from each. In a train of consecutive thoughts we spontaneously weave external stimuli with concepts or experiences that are related, sometimes superficially, and other times through abstract or metaphorical resemblances. That is, experience has a thread of continuity. Sparse, distributed memory [Kanerva 1988], or SDM, is a mathematical model of the mechanics underlying the storage and retrieval of memories that nicely captures these aspects of cognition.

Kanerva draws an analogy between the focus and a combined address-datum register in a computer; they both contain data and serve as a pointer to memory, and can both read from and write to memory. An instant of experience is encoded in the focus by a high-dimensional vector of difference relations, or bits, that represent the presence or absence of some feature, and the mathematics generalizes such that a pattern of bits can represent a value along some dimension. The Hamming distance between two memes is the number of bits that differ. (So the Hamming distance between 11111 and 11100 is two.) Since each meme has an antipode (for example, the antipode of 11111 is 00000), the space of all possible memes can be visualized as a sphere. The address of a meme is the information pattern that specifies where the meme is stored.

If L is the number of possible features in a meme, the number of possible memes is 2^L . Assuming L is large the size this space is enormous, so the memory is sparse in that it stores only a small fraction of the set of all possible memes. For example, to construct a SDM with $L=1,000$, then out of the $2^{1,000}$ possible addresses, a workable number of them, say 1,000,000, are chosen at random to be actual storage locations. The number of memes at Hamming distance k away from any given meme is equal to the binomial coefficient of L and k , which is well approximated by a Gaussian or normal curve. If meme X is 111...1 and its antipode 000...0, and we consider meme X and its antipode to be the poles of the hyper sphere, then approximately 68% of the other memes lie within one standard deviation (\sqrt{L}) of the equator region between these two extremes. As we move through Hamming space away from the equator toward either Meme X or its antipode, the probability of encountering a meme falls off sharply by the proportion \sqrt{L}/L . In our example, the median distance from one location to another is 424 bits, and 99.8% of stored memes lie between 451 and 549 bits of any given location.

A computer reads from memory by simply looking at the address in the address register and retrieving the item at the location specified by that address. The sparseness of the SDM prohibits this kind of one-to-one correspondence, but it has two tricks up its sleeve for getting around this problem.

First, it feigns content addressability, as follows. The particular pattern of 1s and 0s that constitutes a meme causes some of the synapses leading out from the focus to be excited and others inhibited. The locations where memes get stored are memory neurons, and the address of a neuron amounts to the pattern of excitatory and inhibitory synapses from focus to memory that makes that neuron fire.

Activation of a memory neuron causes the meme to get written into it. Thus there is a systematic relationship between the memes' information content and the locations they activate.

Second, since the probability that the ideal address for storing a meme corresponds to an actual location in memory is vanishingly small, storage of the meme is distributed across those locations whose addresses lie within a sphere (or more accurately, hypersphere) of possible addresses surrounding the ideal address. The radius (in Hamming metric) of this sphere is determined by the neuron activation threshold. Each location participates in the storage of many memes. In this example we assume that 10,000 memes have been stored in memory. Each meme is stored in 1,000 (of the 1,000,000 possible) locations, so there are approximately 10 memes per location. The storage process works by updating each of the L counters in each location; to store a 1 the counter is incremented by 1, and to store a 0 it is decremented by 1. These nearly one million operations occur in parallel.

If after a meme, say meme X , is stored, the individual's attention is directed toward external stimuli, then nothing is retrieved from memory. But to the extent that memory contributes to the next instant of awareness, the storage of X activates retrieval of not only X itself but all the other memes that have been stored in the same locations. The next meme to be encoded in the focus, X' , is found by determining the best match; that is, by averaging the contributions of all retrieved memes feature-by-feature. Whereas the 1,000 retrieved copies of X (and memes similar to X) reinforce one another, the roughly 10,000 other retrieved memes are statistically likely to cancel one another out, so that X' ends up being similar to X . Though X' is a reconstructed blend of many memes it can still be said to have been retrieved from memory. X' can now be used to address the memory, and this process can be reiterated until it converges on meme Y that satisfies a current need. This is how the SDM accomplishes depth-first search. The closer Y is to X , the faster the convergence. In our example, assuming $r = 425$, if X and Y are more than 200 bits apart Y is unlikely to be retrieved, but if they are 170 bits apart Y will be retrieved in about four iterations.

Keeler [1988] has shown that SDM is a superset of Hopfield-type and connectionist models of auto associative or hetero associative memory. The SDM formulation is used here because it lends itself to an understanding of the mechanics of phenomena we are interested in. Because of how the dynamics emerges from the statistics, rather than from a central executive, it can cope with creative and seemingly unmechanical cognitive phenomena such as wordplay or slips of the tongue. Moreover it is ideally suited to handle the problem of sequential access, which will become relevant when we look at how an infant establishes a train of thought. To model the recollection of a sequence, meme X is simply used as the address to write Y , Y as the address to write Z , and so on. Working memory can be viewed as the memes that lie within a given Hamming distance of the meme in the focus such that they are retrievable within a certain number of iterations. Categorization could involve the identification of a pattern, and readdressing memes that contain this pattern so that their new addresses put them within working memory reach of one another. Kanerva shows that the architecture of common neural components and circuits in the brain are ideally suited to implement a SDM.

In SDM, associations between memes are not explicitly represented as connection strengths but as proximity in multidimensional space. However in the end they amount to the same thing.

The smaller the Hamming distance between two memes, the higher the probability that they will be retrieved simultaneously and blended together in the focus (or one after the other in a chain of related thoughts). What allows them to be retrieved simultaneously, however, is that they are either stored in the same neurons or in neurons with nearby addresses, which in turn reflects the neurons' connectivity. Thus factors that affect the storage of a meme will also affect retrieval of that meme; the two processes are intimately connected.

6. MEME REPLICATION AND TRANSMISSION

The memetic approach to cognition is not incompatible with approaches that stress the role of innate mechanisms [e.g. Pinker 1995]. Rather, as Lumsden and Wilson [1981] point out, it builds on this framework, adding that the study of cognition will flounder until we admit that the role of transmission is equally undeniable. Transmission links the memetic processing within an individual to not only memetic processing in other directly-encountered individuals, but processing in individuals they encounter, and so on. The ideas and inventions any one individual produces build on the ideas and inventions of others. This phenomenon is known as the ratchet effect, and its impact is demonstrated in the following example. If you were suddenly dropped into the Australian desert, you probably would not survive for long. However if you were to run into an aborigine who grew up learning desert survival skills from her family and community that had been passed on and improved upon for generations (such as how to find water in obscure places) you might survive for some time [note 4].

6.1 INTRA-HOST MEME REPLICATION VIA IMPLICIT POINTERS TO MEMORY

We saw how, unlike genetic material, memes do not contain instructions for how to make copies of themselves; they replicate when their hosts teach or imitate one another. The memes in a SDM-like memory, however, have a self-replication capacity in the following sense. The pattern of information that constitutes a meme determines which of the synapses leading out from the focus are excited, and which are inhibited--it determines how activation flows through the memory network--which in turn determines the neurons where the meme is stored and from which the next meme is retrieved. Thus embedded in the neural environment that supports their replication, memes act as implicit pointers to memory. These pointers prompt the dynamic reconstruction of the next meme to be subjectively experienced, which is a variation of (statistically similar to) the one that prompted it. It is in that sense that they self-replicate.

6.2 TRANSMISSION IS LAMARKIAN AND PHENOTYPICALLY MEDIATED

Internal replication (with variation) makes cultural transmission Lamarckian—modifications acquired since the acquisition of a meme can be passed on to others [Dawkins 1976]. The related point that transmission is phenotypically mediated, as Dennett [1995] points out, makes a science of memetics less daunting. It means that, unlike biologists, we don't have to fully understand the nature of mental representation to study transmission.

6.3 ALL STIMULI SCULPT MEMES

While biological needs affect the focus from the inside, environmental stimuli impact it from the outside. The information-based orientation supports a broader conceptualization of the transmission process than is generally taken. Transmission often occurs through imitation of conspecifics [Smith 1977; Bonner 1980; Robert 1990], or guided instruction [Vygotsky 1978; Tomasello et al. 1993], but not necessarily. For example, does it matter whether a child learns to peel a banana by watching her mother, or a monkey, or a cartoon character on TV? What matters is that the child has a mental representation of how to peel a banana. All interaction between an organism and its environment sculpts the worldview, even if just to increase the organisms' assessment of the probability of encountering a certain stimulus. Therefore all stimuli can potentially affect the interplay of ideas and emotions that evolve through culture.

7. A SCENARIO FOR THE ORIGIN OF COGNITIVE EVOLUTION

We have discussed how memes evolve through selection, variation, replication and transmission. We now address the issue of how this second form of evolution might have begun in the first place.

7.1 THE ORIGIN OF LIFE AND ITS COGNITIVE ANALOG

The origin of life poses the following paradox: how could something as complex as a self-replicating molecule arise spontaneously? Traditional attempts to explain this entail the synchronization of a large number of vastly-improbable events. Proponents argue that the improbability of the mechanism they propose does not invalidate it because it only had to happen once; as soon as there was one self-replicating molecule, the rest could be copied from this template. However Kauffman [1993] proposes an alternative scenario that does not entail the synchronization of numerous improbable events. He suggests that life arose through the self-organization of a set of autocatalytic polymers. When catalytic polymers interact with one another their average length increases. As their length increases, the number of reactions by which polymers can interconvert increases faster than the number of polymers. Therefore a set of interacting molecules under conditions such as are likely to have existed at the time life began would inevitably reach a critical point where there is a catalytic pathway to every polymer present. Jointly they form a self-reproducing metabolism.

We now ask: What is the cultural analog to the origin of life? One could say it is the point in history when organisms acquired the capacity for social transmission, but as many authors [e.g. Darwin 1871; Plotkin 1988] have pointed out, although transmission is wide-spread throughout the animal kingdom, no other species has anything remotely approaching the complexity of human culture. Donald [1991] argues convincingly that the bottleneck in cultural evolution is the capacity for innovation. Innovation requires more than a kind of awareness that integrates survival needs with environmental affordances, and draws upon memory only to interpret stimuli, or consult a mental map, or recall how some drive was satisfied in the past. It requires an ongoing train of creative representational redescription and counterfactual 'what if...' type thinking. This suggests that the cultural analog to the origin of life was the origin of the first self-perpetuated, potentially-creative stream of thought in an individual's brain.

When an infant has its first experience, there is nothing in memory to draw upon to contribute to that experience; the first meme to occupy its focus does not remind it of anything. Therefore experience is initially driven only by external or internal stimuli, not by memory. Thus the evolution of culture poses a paradox analogous to that of the origin of the self-replicating molecule how does an infant develop the capacity for a self-sustained train of thought that creatively integrates new experiences with previous ones? Consistent with Kauffman's assertion that the bootstrapping of an evolutionary process is not an inherently improbable event, the 'it only had to happen once' argument does not hold water here because the cultural analog to the origin of life takes place in the brain of every infant.

7.2 ESTABLISHING AN AUTOCATALYTIC SET OF SPARSE, DISTRIBUTED MEMORIES

This section outlines how a SDM-like stream of thought might get established. Let us say that the first meme to occupy an infant's focus and then get stored in memory is a visual experience of its mother in a blue coat. The next is the sound of a dog barking. The Hamming distance between these memes exceeds the maximum for one meme to evoke the memory of another, so the barking does not remind the infant of its mother. Later the infant sees its mother in a red coat. This meme evokes or catalyzes the memory of its mother in a blue coat. To avoid getting stuck in an endless loop wherein 'mother in blue coat' then evokes 'mother in red coat' et cetera, it may form the category 'mother'. However that meme does not remind it of anything, so this stream of thought dies off quickly.

As the infant accumulates memes, the statistical probability that a meme in the focus will activate a meme from storage increases, so the streams of reminders get longer. Eventually the memory becomes so densely packed that any meme that comes to occupy the focus is bound to be close enough in Hamming distance to &some previously- stored meme(s) to activate a variant of itself. This marks a phase transition to a state in which, just as with the origin of life, the sequential activation of self-similar patterns is self-propelled; the memes now form an autocatalytic set. The focus is no longer just a spot for coordinating stimuli with action, but a forum for the variation-producing operations that emerge naturally through the dynamics of iterative retrieval. The resultant memes evolve along different trajectories toward different basins of attraction, specializing in the fulfillment of one need or another. Those that satisfy the same need compete until one becomes habitual, while those that fulfill different needs are able to coexist within the same host. As with biological speciation, small differences are amplified through positive feedback leading to transformation of the space of viable niches for the evolution of information patterns.

Note that in this example the 'mother' meme is the infant's first category. A simple way of describing this situation is: if the 'mother in blue coat' meme is represented as 111, and the 'mother in red coat' meme is represented as 110, the 'mother' meme can be represented as 11*, where * means either 1 or 0. It is also the infant's first derived meme. That is, it is the first information pattern to enter the focus not purely by way of external stimuli but through the necessity of a logical operation on previously-stored memes--in this case an OR gate--which could be realized in the brain via adjustment of connection strengths. The act of categorization projects the original information space, which had n relevant dimensions, onto a new space that

has $n-1$ dimensions (for example, here coat color is no longer relevant). It effectively makes the space denser, and increases susceptibility to the autocatalytic state. On the other hand, creating new memes by & combining previously-stored memes could interfere with the establishment of a sustained stream of thought by increasing the dimensionality of the space, thereby decreasing density. If indeed cross-category blending disrupts conceptual autocatalysis, one might expect it to be less evident in young children than in older children, and this expectation is born out experimentally [Karmiloff-Smith 1990].

Note also that the density of memes necessary to reach and maintain this autocatalytic state will depend on the neuron activation threshold. If the threshold is too high (the hypersphere of potentially activated memes is too small) even very similar memes cannot evoke one another, so a stream of reminders, if it happens at all, dies off readily. If the threshold is too low (the hypersphere too large), then any meme will evoke a multitude of others not necessarily meaningfully related to it. Successive patterns in the focus will have little or no resemblance to one another; the system may be catalytic but it is not autocatalytic. The free-association of the schizophrenic [see Weisberg 1986] seems to correspond to what one might expect of a system like this. For memory to produce a steady stream of meaningfully-related yet potentially creative reminders, the threshold must fall within a narrow intermediate range. This is consistent with Langton's [1992] finding that the information-carrying capacity of a system is maximized when its interconnectedness falls within a narrow regime between order and chaos. The situation may turn out to be slightly more complicated; sustaining a creative train of thought may involve not only keeping the activation threshold within a narrowly-prescribed range but dynamically tuning it in response to the situation at hand. This is particularly likely if the memory is not uniformly dense (i.e. clusters of highly-correlated memes) or if different kinds or stages of thought require different degrees of conceptual blending. For example, finding unusual associations may depend on the preconscious ability to temporarily increase hypersphere radius.

Thus we have a plausible scenario for how cultural evolution, like biological evolution, could have originated in a phase transition to a self-organized web of catalytic relations between patterns.

8. WHY IS CULTURE UNIQUE TO HUMANS? A SPECULATIVE ANSWER

Recall that in order for a network of memes to reach an autocatalytic state, the activation threshold must be calibrated to fall within a narrow range to achieve a delicate balance between the capacity for semantic continuity on the one hand and creative association on the other. The penalty for having too low a threshold would be very high; successive thoughts would not necessarily be meaningfully related to one another, and thinking would be so muddy that survival tasks are not accomplished. Too high a threshold, on the other hand, would not be life-threatening. The focus would virtually always be impacted with external stimuli or internal drives such as hunger; memory would be pretty much reserved for recalling how some goal was accomplished in the past. A stream of experience that involved the iterative reorganization of stored memes would likely die out before it produced something creative. This may be the situation present in most brains on this planet, and the reason that apes are limited to episodic memory [e.g. Donald 1991].

The advantages of a sustained train of thought would be largely lost on animals because they have neither the vocal apparatus nor the manual dexterity and freedom of upper limbs to implement complex ideas. No matter how brilliant their thoughts were it would be difficult to do something useful with them. Moreover, in an evolutionary line there is individual variation, so the lower the average activation threshold, the higher the fraction of individuals for which it is so low that they do not survive.

These ideas are of course very speculative. However it seems reasonable to suggest that apes are not a priori prohibited from evolving complex cognition, but that there is insufficient evolutionary pressure to tinker with the activation threshold until it achieves the requisite delicate balance to sustain a stream of thought, or to establish and refine the necessary feedback mechanisms to dynamically tune it to match to the degree of conceptual fluidity needed at any given instant. It may be that humans are the only species for which the benefits of this tinkering process have outweighed the risks.

9. A COMPUTATIONAL APPROACH

Meme and Variations, or MAV [Gabora 1995] is a computer model of a society composed of interacting neural network- based agents. Unlike other such models that combine biological and cultural evolution [e.g. Ackley 1994; Spector & Luke 1996] these agents don't have genomes, and neither die nor have offspring, but they can invent, implement, and imitate memes. MAV successfully evolves patterns of information through cultural implementations of variation, selection, and replication, and exhibits phenomena observed in biological evolution such as: (1) drift--random statistical bias due to sampling error [Wright 1951; Cavalli-Sforza & Feldman 1981] (2) epistasis increases time to reach equilibrium, (3) increasing frequency of variation-generating operations increases diversity, and (4) although in the absence of variation-generating operations meme evolution does not occur, increasing variation-generation much beyond the minimum necessary for evolution causes average fitness to &decrease. MAV also addresses issues specific to cultural evolution, such as the effects of mental simulation, imitation, and strategy. Perhaps the most interesting finding it yielded was that although for the society as a whole the optimal creation-to-imitation ratio was approximately 2:1, for the agent with the fittest memes, the less it imitated (i.e. the more computational effort reserved for creation) the better.

MAV will hopefully serve as a stepping stone to more advanced models of memetic evolution. Of particular interest will be models that: (1) like Tierra, a model of biological evolution [Ray 1991], harness the power of evolution to explore and transform an &open-ended space of possible patterns, but (2) explore the space strategically on the basis of accumulated knowledge rather than at random, (3) have fitness landscapes that emerge through the needs of the agents within the constraints of their environment, and (4) have agents that must learn for themselves which memes, when implemented, best satisfy each of their various needs.

Mathematical models of culture are too minimal to cope with the open-ended diversity of culturally-derived information (variation is generally restricted to trial and error learning or transmission error) let alone address the numerous intra-individual factors that undoubtedly have emergent inter-individual consequences, such as how representations are grounded in experience

and how they are stored, retrieved, and implemented. Models of individual intelligence and creativity, on the other hand, lack transmission and replication.

Although this research may not explicitly attempt to address group processes it typically focuses not on the sorts of simple inferences and creative acts that a person raised alone in the wild would be capable of, but on complex acts such as story comprehension, that might be unlikely to develop in isolation. With the advent of massively parallel computers it is becoming increasingly feasible to place computational models of individual creativity and problem-solving in a cultural context. This approach could provide insight into not only problems pertaining to representation and culture, but evolution in general, through comparison with biology. For example, the question of why there is so much redundancy in the genetic code has generated much discussion which may also apply to the question of why there are redundant mental maps in the brain; both may reflect constraints on the nature of an information-evolving code.

10. A MEMETIC PERSPECTIVE ON PSYCHOLOGICAL CONCEPTS

We turn now to how the cultural evolution perspective can shed light on some aspects of the human experience.

10.1 MENTAL CENSORSHIP AND INDUCTION

Initially an infant is unselective about meme acquisition, since (1) it doesn't know much about the world yet, so it has no basis for choosing, and (2) its parents have lived long enough to reproduce, so they must be doing something right. However just as importing foreign plants can bring ecological disaster, acquisition of a foreign meme can disrupt the established network of relationships amongst existing memes. Therefore the infant develops mental censors that ward off internalization of potentially disruptive memes. Censors might also be erected when a meme is found to be embarrassing or disturbing or threatening to the self-image [Minsky, 1975]. In a SDM-type architecture this could be accomplished by increasing the activation threshold so as to prematurely terminate the relaxation process and prevent the content of the focus from assimilating with stored memes. Much as erecting a fence keeps people on one side or the other, erecting a censor around a meme would warp the statistical probability that it will partake in the ongoing process of associative recall such that its host either avoids the censored meme or dwells on it excessively. This seems to be consistent with our bipolar attitude toward highly censored subjects such as aggression and sexuality.

On the other hand, when the cost of the disruption is outweighed by the potential benefit accrued by a world model that can accommodate the new meme, the threshold would be lowered. Most thoughts seem to have little effect on our understanding of the world at large, but once in a while we experience a meme that significantly modifies our worldview. The situation is reminiscent of superconductivity; lowered resistance increases correlation distance, and thus a perturbation to any one pattern can percolate through the system and affect even distantly-related patterns. It would be interesting to determine experimentally whether the inductiveness of our memes, like other self-organizing systems, exhibits the ubiquitous inverse power law [Bak, Tang & Weisenfeld 1988]. Just as in a sand pile perched at the proverbial edge of chaos once in a while a collision between two grains will lead to another in just the right chain reaction to generate a

large avalanche, occasionally one thought will trigger a chain reaction of others in a way that reconfigures the conceptual network.

10.2 THE UNCONSCIOUS

The concept of the unconscious has been influential and useful despite the obvious incongruity: how is it that we can consciously discuss something that is unconscious? What we may be referring to is the fleeting experience of memes that are dynamically reconstructed as in a SDM but which do not readily assimilate with other memes and so get discarded from the focus. In other words, the need for worldview consistency prohibits further computational resources from being spent on trying to integrate what appears to be a nonsensical construction into the memory. Of course there is no reason why a meme that is not immediately integrated into the memory might nevertheless affect the memory; the very process of determining whether it can be assimilated or not might itself have effects that infiltrate the system. This possibility is supported by the finding that subjects' behavior can be affected by priming material of which they have no recall [e.g. Dunbar & Schunn 1990; Fehrer & Raab 1962]. Subconscious processing of this sort could, in fact, resculpt the memetic fitness landscape in such a way that a previously- discarded meme is more readily assimilated the next time it is encountered.

10.3 CULTURAL MOMENTUM

Despite being derived, directly or indirectly, from human need, memes do not always promote our survival [Greene 1978; Alexander 1980]. As Dawkins [1982] points out, "It is true that the relative survival success of a meme will depend critically on the social and biological climate in which it finds itself, and this climate will certainly be influenced by the genetic make-up of the population. But it will also depend on the memes that are already numerous in the meme-pool." Much like runaway selection in biology, once a meme can replicate with variation on the basis of some selection criterion, it can evolve out of the orbit of the need that originated it. We can't help but engage in a stream of thought, spontaneously generating new memes like 'if only such and such had been different...', any more than biological evolution can help but generate new species. This cultural momentum could explain why, despite the intuition that individuals control their streams of thought, creators often express surprise at the sudden appearance of an idea, and deny active effort in its immediate creation [Bowers et al 1990; Guilford 1979; Kubose et al 1980; Wallas 1926]. We seem to control the birth of our ideas only to the extent that we provide a fertile ground for them to be fruitful and multiply by internalizing relevant background knowledge, identifying new needs, and exposing ourselves to stimuli that help trigger ideas that fulfill those needs. (So if you don't like this idea, don't blame me.)

Spurious basins of attraction sometimes arise in recurrent neural networks through the compositional interaction of explicitly-trained attractors [Hopfield 1982]. Cultural momentum may boil down to a phenomenon of this sort. Just because the memetic fitness landscape largely echoes the biological fitness landscape, that doesn't mean that behavior elicited by memes in spurious basins of attraction arising through representational redescription need always be conducive to survival. Nevertheless a stream of thought could be censored before it elicits harmful behavior. Streams of thought probably get blocked or sidetracked on a regular basis, not just by censors, but by minute-to-minute undulations in the hyper-dimensional fitness landscape,

that is, change in the relative urgency of the multitude of survival-related or derived needs impacting the focus.

The concept of cultural momentum sheds light on the issue of free will. Those who argue for the existence of a central executive in memory may come to be viewed as the creationists of philosophy and cognitive science. Human will can instead be viewed as the emergent orchestration of needs, stimuli, and retrieved memories impacting the focus, which is subject to cultural momentum and therefore, in a sense, beyond our control.

10.4 THE BIRTH OF IDEAS

The biologically-inspired model developed here supports a variant of the combination theory of creativity that new ideas arise through combinations and transformations of old ones [Boden 1991; Koestler 1964]. The aspect of this theory that does not ring true is that it neglects the role of emotions. Here we consider emotions, as well as ideas, to be encoded as information in memes; some components of a meme are simply interpreted by parts of the mind that experience them as emotion, whereas others are interpreted by parts of the mind that experience them as ideas. Much research on analogy deals with how the structure or conceptual skeleton underlying one idea gets abstracted and applied to another [Gentner 1983; Gick & Holyoak 1983]. We can expand on this general idea by suggesting that many forms of creative expression begin with the (unvoiced) question: What would the pattern of information that encoded the emotion I experienced during this particular event look like if expressed through the constraints of that medium? The existence of inherent limitations on how a pattern could translate from one domain to another is consistent with the frequent observation that creativity involves both freedom and aesthetic constraint. Thus all creativity is directly or indirectly derived from experience in the world, and since the mathematics underlying this world, the set of all natural functions, is a small subset of all &possible functions, the constraints that guide creation are not arbitrary but objective and familiar; for example the drum beat of a song might echo a heartbeat, when the rhythm and chord progression are reminiscent of the sound of someone sobbing we feel sad, and we hear the wrong note even if we have never heard the song before.

It makes sense to expect that a meme or meme complex that has been censored (for example because it evoked unbearable sadness or anger) would be vulnerable to being targeted as an area where worldview cohesion could be increased. Since at the time the censored material was experienced it was prohibited from forming associations to obviously-related memes, it in turn can not be retrieved through these expected or straightforward associations. It can only be retrieved via backdoor entrances, which are associations that reflect structural congruity at an abstract level. Thus a musician may come to habitually funnel patterns encountered in a variety of domains—and particularly censored material—through modules that filter out hitchhiker and enabler features, and adapt the core features (or feature schemata) to the constraints of music. It is in this repackaged format that memes originally deemed dangerous can be integrated into the memory at large without harm, and it is through this process that the creator establishes a sense of control over memes that were previously off-limits.

The account proposed here may seem too simple to explain the seemingly limitless human potential for creativity, but it may seem less far-fetched when we consider the variety of species

produced by biological evolution, which operates without the benefit of strategy. Furthermore, raw materials for the creative process may be acquired in exceedingly subtle ways. It is conceivable that you might watch a stream flow and without your consciously thinking, 'It flows... things can flow... I could even, in some sense, adopt a more flowing approach to life', the experience might be reconfiguring your memetic infrastructure in a way that makes you more easygoing. I am not making any claims about the extent to which experiences of this sort affect us or even whether they occur at all, but rather suggesting that we not prematurely place a lid on the kinds of processes that could affect a network of representations and thereby affect creation and transmission.

10.5 MEMETICS AS MISSING LINK BETWEEN SCIENCE AND SPIRIT

Recall that to implement a meme is to express it, so that it crystallizes from the world of ideas into words or body language or objects in the physical world. Memes fool potential hosts into wanting or identifying with them, by aligning themselves with memes we already hold dear (as advertisers are well aware). The more we value ourselves in terms of the memes and implemented artifacts we possess or lack, the more vulnerable we are to ever-more-seductive forms of persuasion and advertising which tie up time, energy, and resources that could be applied toward other goals.

One way to defend oneself against painful or manipulative memes is to construct what Dennett [1995] refers to as a meme-immunological system; that is, formulate new memes specifically to deflect memetic antigens. However constructing memetic antibodies of this sort is time-consuming, and like any immunological response it has to be repeated every time the outside agent evolves a counter-response.

Perhaps this explains the purported benefits of transcending the ego [e.g. Walsh & Vaughan 1993], which can be taken to mean getting in touch with who we were before our minds were colonized by memes, through practices such as meditation. These practices may work by giving the brain time to anneal material that was never fully assimilated because of distraction or censorship--mend flaws in the fabric of the individual's worldview. Release from the restrictive power of censors may then enhance the individual's raw 'sense of self' and produce a feeling of unity or one-ness.

It is almost impossible to discuss creative insight or spiritual unfoldment without drawing upon metaphors involving light. For example: her face lit up, he glowed with enthusiasm, moment of illumination, reflect on an idea, dim-witted person, and dark night of the soul, to mention a few. Even nonverbal communication uses these metaphors; everyone knows that when a light bulb appears above Charlie Brown's head he has had a 'bright' idea. Experiences of inner light have been documented since the dawn of civilization. Some cultures have a name for it; Eskimo shamen call it qaumaneq, while Vedanta Hindusists refer to it as Atma. Lao-tzu advised his people "Use the light that is within you". The Gnostics described flashes of insight or discovery as "light sparks" or scintillae, and they conceived of the soul as a radiant sphere that is prone to contamination, in which case it darkens and becomes more material. Indra's Net is a Buddhist allegory about a net of threads stretching horizontally through space and vertically through time, and at every crossing of the threads is a crystal bead that represents an individual. Buckminster

Fuller spoke of the soul as a bright sphere of awareness that moves wherever the individual moves. Jung suggested we think of ego-consciousness as "surrounded by a multitude of little luminosities".

Since we know the physical world largely through how light of various frequencies reflects off objects, it is perhaps natural that we use something analogous to also make sense out of the world of abstract ideas and emotions. In diagrams of SDM or neural networks, when a meme or meme feature becomes active it is generally represented as lit up. These diagrams may be derived from the same kind of intuitive understanding as the mystical experiences mentioned above. They may turn out to be early prototypes for a portrayal of spiritual knowledge that is real in the same way as a pie chart of business expenses represents something real. We may be on the doorstep of an era when spiritual experience not only rings true, but makes logical sense as well.

10.6 MEMETICS AND WOMENUS STUDIES

One of the things I hope the study of memetics will one day shed light on is the cumulative effect on women's self esteem of encountering the default 'he' or 'his', or phrases like 'man and his world'. Each time it happens, it reinforces, however subtly, the thought "I'm not one of the important ones", or "that doesn't pertain to me so I don't really count". The effect of this may be insignificant the first few, or even hundred times, it happens. But by the time a young girl reaches adulthood, experiences of this kind probably number in the millions, and that may be when the effects start to kick in.

11. A MEMEUS-EYE VIEW

In this section we examine a hypothetical and admittedly speculative scenario for how evolutionary concepts borrowed from biology might apply to the dynamics of a specific meme.

11.1 THE ONTOGENY OF A MEME

One day a classroom bully named Tony put his arm around a girl named Memela. Memela felt threatened by Tony's advance. Her first impulse was to get angry but she censored this reaction. The need for worldview cohesion motivated a desire to escape the restrictive power of this censor and find a backdoor vent for her anger. Eventually she whispered to a classmate: "Tony Testosteroni made a pass at me." Thus began the era of Memela's meme.

Memela's meme can be traced back to a number of precursor or protomemes, many of which originated in the minds of family and friends and were subsequently transmitted to Memela. These protomemes provided an environmental niche in which the joke could flourish. But Memela was more prone to this kind of humor than her siblings. A sort of conceptual speciation had taken place in their brains, wherein small initial differences were amplified through positive feedback, and Memela had become known as the jokester.

Perhaps Memela was predisposed to produce the joke because her brain spontaneously exerts a high degree of control over its activation threshold. Her ability to find unusual associations by

increasing hypersphere radius, and subsequently refine a train of thought by decreasing the radius, facilitates word play such as the establishment of epistatic relationships between semantic and syntactic features of a meme. The semantic applicability of the word testosterone to Tony's aggressive behavior, and the alteration of this word to make it sound Italian and echo the syntax of (i.e. rhyme with) the Italian first name, contribute to the humor of Memela's meme. Its relation to the highly censored subjects of aggression and sexuality may also have added to its appeal.

11.2 A DAY IN THE LIFE OF MEMELA'S MEME

This kind of conceptual epistasis provokes laughter, which draws attention to a meme. Memela's meme took full advantage of this. When Memela told the joke to one of her classmates the ensuing laughter attracted a small crowd of other potential hosts, and within an hour Memela's meme had reached most of the students in the classroom. Their willingness to invest time acquiring this meme was a smart move; the joke not only provided amusement, but it proved to be a useful precursor to the formulation and understanding of subsequent jokes in this social circle. Some were direct descendants of Memela's meme, such as jokes along the lines of "What's for lunch--rigatoni a la testosteroni?" Others were more distantly related, such as nicknames for other classmates that arose because Memela's meme had activated the general concept of nicknaming. Across the classroom, ideas that pertained to nicknaming came to constitute a highly active region of conceptual space.

By the time recess ended it had migrated extensively through the school population. There were certain subpopulations of individuals it failed to penetrate, such as social outcasts who were excluded from much of the memetic exchange. These individuals' minds exhibited a cultural version of the Founder Effect [Holgate 1966]--reduced variation in a small population due to genetic drift. Memela's meme also failed to reach students who engaged in projects that took them away from the playground at recess. However since these individuals had had less opportunity to witness Tony's behavior, they had less need to diffuse their fear of him. Thus even if they had heard Memela's meme they did not possess the necessary precursor memes to fully appreciate it; the prerequisite memetic niches were not in place. At any rate despite its failure to reach these subgroups, Memela's meme experienced a high degree of memetic fitness. It migrated far beyond the classroom in which it was originally formulated, reconfiguring networks of representations in ways that affected the subsequent thought and behavior of a number of individuals. The telling of this meme and its various incarnations constituted an act of memetic altruism between like-minded individuals analogous to the biological altruism that occurs between genetically-similar individuals. It played a small role in an ongoing network of positive reciprocal interactions through which there emerged a memetically-derived social structure wherein individuals that regularly generated pleasurable or powerful memes came to be observed carefully and imitated frequently, while other individuals were ignored. Thus the fate of Memela's meme and its descendants reflected the social and psychological dynamics of an entire society of interacting individuals.

Like the other students in the classroom, Tony was affected by the sound of laughter advertising the presence and amusement value of Memela's meme. However it wasn't until someone told him that it was a joke was about him that he felt willing to do almost anything to hear it. Upon

hearing the nickname Tony felt ridiculed. In the case of Memela's meme a meme-immunological system could be something along the lines of "That nickname is silly and stupid."

12. CAN MEMETIC EVOLUTION PROVIDE A SYNTHETIC FRAMEWORK FOR THE COGNITIVE AND SOCIAL SCIENCES?

This chapter gives us a taste of how the concept of evolution may be able to provide the kind of overarching framework for the humanities that it provides for the biological sciences. It sketches out a theoretical framework for cultural evolution, adopting an approach analogous to that of the population geneticist in that it emphasizes meme evolution through social interaction and de-emphasize individual hosts. Although the cultural evolution of memes operates through very different mechanisms from those of biology, culture is the only system comparable to biology, because it is the only other system to exhibit the imperative features of evolution adaptive exploration and transformation of an information space through variation, selection, and transmission. All patterns in the information we encounter can be traced to either (1) the physical constraints and self-organizing properties of matter, (2) biological evolution, (3) cultural evolution, or (4) interactions between these causal principles.

One important difference between the two forms of evolution is that culture is less random--new patterns have a greater-than-chance probability of being more fit than their predecessors. The reason for this is interesting. Since memes (unlike genomes) do not come packaged with instructions for their replication, they must rely on the pattern-evolving machinery of our brains to do it for them. Ironically, this state of dependence enhances their proliferative potential, because the machinery they depend upon constructs and continually updates mental models of its world--that is, weaves the memes into a worldview--and uses this worldview to enhance the assimilation and implementation of the memes and their offspring.

Cultural evolution presents a puzzle analogous to the origin of life: the origin of a self-sustained stream of potentially-creative thought in an infant's brain. The idea that life originated with the self-organization of a set of autocatalytic polymers suggests a possible mechanism for how this comes about. Once a threshold density of assimilated memes is surpassed, any meme that occupies the focus is close enough in Hamming distance to evoke or 'catalyze' the spontaneous retrieval or creative reconstruction of a statistically similar meme, thus the memes form an autocatalytic set. Note that this macroscopic account suggests an explanation for only that aspect of human consciousness that differentiates us from other 'experiencers'; it does not address the mystery of 'raw awareness' that some say characterizes not only our experience but that of a cow or a mosquito or even a thermostat [e.g. Chalmers 1996]. Whether or not this specific theory turns out to be correct, it illustrates how the analogy to biology can focus our study of culture by providing a scaffold around which explanatory theories can be built.

The cultural framework for cognition developed here suggests tentative explanations for psychological phenomena such as censorship and creativity, and why they are virtually unique to humans. It also suggests explanations for various social phenomena.

There is good reason to view the mind as a memetic host—a generator, selector, and replicator of cultural information—and society as a continually-regenerated constellation of such hosts.

Interactions in the world affect our memetic structure, which in turn affects future interactions, and these interactions allow cultural information to evolve, recursively and in parallel in its many hosts. With each new generation of hosts, the conceptual infrastructure from which memes are born and grow reflects how memes were encoded and implemented by the previous generation. I cannot imagine a more exciting role to play in this process than partaking in the exploration of memes about memes.

MEMES: THE CREATIVE SPARK

By
Liane M. Gabora

Memes, unlike genes, do not come packaged with instructions for their replication; they rely on the pattern-evolving machinery of our brains. We tend to replicate memes that satisfy needs - biological needs like food, shelter, and sex, or needs that contribute less directly to survival of self and progeny. These include the need for love, and the need for a coherent internal model of the world, something we can call upon whenever a situation is too complicated for our hardwired instincts.

This worldview weaves each new instant of experience into its tapestry of associations. Mental censors, however, can disrupt the assimilation of memes that threaten the individual's ego or belief structure. This prevents the brain from forging associations between the new meme and previously stored memes. Conversely, insightful memes sometimes trigger a chain reaction that modifies their host's entire worldview - a conceptual phase shift. Since brains are wired so that related memes trigger one another domino style, cultural evolution, like biological evolution, has built-in momentum. We control the birth of "our" memes only to the extent that we provide a fertile ground for them to grow and multiply.

The brain's tendency to play with its memes, continually reorganizing and ironing out arbitrary associations to forge more meaningful ones, often creates unanticipated solutions to pressing problems. This suggests that creativity, the fountainhead of cultural variation, is strategic - not random, as are the variation-generating processes in biology.

Another consequence of meme play is that knowledge or emotion encoded in one kind of experience can be translated into another kind of experience. The tension produced by censored sexual material, for example, might be diffused in a joke. Or a musician may come to habitually funnel memes encountered in all types of situations - particularly censored material - through brain modules that filter out domain-dependent elements and adapt the core components to the constraints of music. It is in this repackaged format that memes are more fully integrated into their host's memory, and it is through this process that the creator establishes a sense of control over memes that were previously off-limits. Creativity is thus directly or indirectly derived from experience in the world, and since the mathematics underlying this world - the set of all natural functions - is a small subset of all possible functions, the constraints that guide creation are not arbitrary. The drumbeat of a song might echo a heartbeat, and when rhythm and chord progression suggest the sound of someone sobbing, we feel sad.

Memes, as advertisers are well aware, can fool potential hosts into believing they are needed by associating with memes we already identify as necessary. It takes time to degrade these unwarranted associations and assimilate memes that were previously censored - in other words, to mend flaws in the fabric of the individual's worldview. Thus the power of meditative practices: release from the isolating restriction of censors creates a feeling of oneness. Transcending the ego can be taken to mean getting in touch with that part of ourselves that

existed before our minds were colonized by memes, often visualized as a spark, halo, or sphere of light.

If each field of knowledge is a pile of sand, the overlapping sandpiles of our era have begun to fuse into one big block. Perhaps the 21st century will see the entire slab of human knowledge stood on its side, and with the help of a new breed of sciences that are not just interdisciplinary but transdisciplinary, we will carve slices that run perpendicular to all the traditionally defined disciplines, encompassing part of each. Memetics appears not only to put us on the road to understanding the pervasiveness, diversity, and adaptive complexity of the cultural debris that surrounds and infests us. It also yields unexpected insight into creativity and spiritual matters that have mystified us since the first fledgling memes appeared in our ancestors' brains.

Liane M. Gabora (liane@cs.ucla.edu), a research fellow at UCLA's Center for the Study of the Evolution and Origin of Life, serves on the editorial board of the Journal of Memetics (www.fmb.mmu.ac.uk/jom-emit/). She is working toward putting together an animation/artificial life/motion capture/dance laboratory for applied research into the oldest form of memetic exchange: body language.

THE ORIGIN AND EVOLUTION OF CULTURE AND CREATIVITY

Abstract

Like the information patterns that evolve through biological processes, mental representations, or memes, evolve through adaptive exploration and transformation of an information space through variation, selection, and transmission. Since unlike genes, memes do not come packaged with instructions for their replication, our brains do it for them, strategically, guided by a fitness landscape that reflects both internal drives and a worldview that is continually updated through meme assimilation. This paper presents a model for how an individual becomes a meme-evolving agent via the emergence of an autocatalytic network of sparse, distributed memories, and discusses implications for complex, creative thought processes and why they are unique to humans. Memetics can do more than account for the spread of catchy tunes; it can pave the way for the kind of overarching framework for the humanities that the first form of evolution has provided for the biological sciences.

Keywords: autocatalysis, creativity, culture, evolution, imitation, induction, information, meme, memory, mental representation, natural selection, social learning.

1 Culture as a Second Form of Evolution

While some ideas instantly fade into obscurity, others spread horizontally through society, and vertically from one generation to another, getting progressively refined and embellished along the way. Thus ideas, like the strands of DNA that encode instructions for building and maintaining living organisms, seem to undergo a process analogous to biological evolution. Accordingly there has been a slow but steady effort to map the concept of evolution onto the dynamics of culture. Popper [72] and Campbell [11] alerted us to the evolutionary flavor of epistemology. Dawkins [17] introduced the notion of a meme - a replicator of cultural information analogous to the gene. In his words: "Just as genes propagate themselves in the gene pool by leaping from body to body via sperm or eggs, so do memes propagate themselves in the meme pool by leaping from brain to brain." Others have drawn from mathematical models of population genetics and epidemiology to model the spread of ideas (Cavalli-Sforza & Feldman [12], Lumsden & Wilson [56], Schuster & Sigmund [84], Boyd & Richerson [9], Hofbauer & Sigmund [33]).

These works point toward the possibility that memetics constitutes a second form of evolution, distinct from yet intertwined with biological evolution, with the potential to provide the kind of overarching framework for the social and cognitive sciences that the first form provides for the

biological sciences. However thus far memetics has not lived up to this potential, a situation that seems unfortunate given the success of the biological precedent. Although much was known about living things before Darwin, his theory of how life evolves through natural selection united previously disparate phenomena and paved the way for further biological inquiry.

Some believe that looking to biological evolution to gain insight into cultural evolution is a waste of time. As Gould [28] put it: "Biological evolution is a bad analog for cultural change... biological evolution is powered by natural selection, cultural evolution by a different set of principles that I understand but dimly." However at an abstract level of analysis they amount to the same thing: exploration and transformation of an information space through variation, selection, and replication. Both present the question of what underlying mechanisms could *launch* a self-perpetuating adaptive process. Thus the possibility that the two have enough in common that the former can pave the way for the latter seems at least worth pursuing. Skeptics may wonder how we can develop a theory of cultural evolution before we understand how memes are instantiated in the brain. This situation has a precedent: Darwin came up with the theory of biological evolution through natural selection before the discovery of genes. It turned out that genes are laid out in a fairly straightforward way in physical space, which does not appear to be the case with memes. This does not mean they can't evolve, so long as there is a way of retrieving the components of a meme so they can work together as a unit. We may not yet know all the physiological details of how the information manifested in, say, a handshake between two individuals - with its unique arrangement of contact points, applied forces, and trajectory - can be traced back to these individuals' mental representations of handshakes, each other, and the situation they are in. But let us proceed with the confidence that a solution exists and can be found.

This paper outlines a theory of how memes evolve, and illustrates how the memetic perspective provides not only not only a foundation for research into the dynamics of concepts and artifacts at the societal level, but a synthetic framework for understanding how mental representations are generated, organized, stored, retrieved, and expressed at the level of the individual. It also sketches a tentative theory of how an infant develops a sustained train of potentially-creative thought and thus becomes a cog in the meme-evolving machinery. Implications of this theory pertaining to the mechanisms underlying creativity, and why it is virtually nonexistent in other species, are explored. It concludes with discussion of how a cultural-evolution perspective can shape and inspire research in the cognitive and social sciences.

1.1 Components of an Evolutionary System

In order for evolution to happen there must be:

- A *pattern of information* (a state within a space of possible states)
- A way to generate *variations* of the pattern (explore or transform the space)
- A rationale for *selecting* variations that are adaptive - tend to give better performance than their predecessors in the context of some problem or set of constraints (a fitness landscape applied to the space)
- A way of *replicating and transmitting* (or amplifying, as molecular biologists refer to it) the selected variations

In biological evolution, the evolving patterns of information are genes encoded as sequences of nucleotides. Variations arise through mutation and recombination, and natural selection weeds out those that are maladaptive. Replication takes place at the level of the genotype. In cultural evolution, the evolving patterns of information are memes - mental representations of ideas, behaviors, or other theoretical or imagined constructs, perhaps encoded as patterns of neuron activation. Variations are created by combining, transforming, and reorganizing representations, consciously or unconsciously, or through errors in transmission. Replication is phenotypically mediated; it occurs when representations are transformed into action or language, transmitted through processes such as imitation, and reproduced, more or less, in another brain.

Incorporation of these new information patterns into the society alters the selective pressures and constraints exerted by the social environment, which in turn leads to the generation of yet more patterns. Thus memes, like DNA, comprise a self-sustained system for the relentless exploration and transformation of a space of possible patterns.

1.2 Culture is Not Just a Predictable Extension of Biological Evolution

The line of reasoning presented here can be succinctly conveyed in terms of *information*, which is related to the number of differences required to specify the state of a system (Shannon & Weaver [85], Bateson [4]). States have not only a structure of difference relations between them, but also a combinatorial structure - each state can itself comprise an information space, so that complex information can be built up from simple information. We can rate each state in a space of possible states against some performance measure or fitness criterion and the result is referred to as a *fitness landscape*, and we can move from one state to another by way of a *computation*. The world can be viewed as a vast network of computations wherein information is created, transformed, and destroyed. This information often exhibits *pattern*, or statistical regularity that can be expressed mathematically.

After seeing many shadows cast by the same object we can develop an internal model of what that object looks like without having seen it, and if more than one object is casting shadows we can learn to tell which object is casting any particular shadow. Similarly, by viewing every pattern we encounter as a shadow or footprint of one or more broad causal principles [note 1], we can gain insight into the causal principles that manifest that pattern.

If you were to go back to sometime during the first billion years of Earth's history, the only causal principle you would need to invoke to explain pattern in the information present (with the exception of yourself) would be the *physical constraints and self-organizing properties of matter*.

If you were to go back to sometime *after* the origin of life, approximately three billion years ago, this would no longer be the case. Not that life doesn't exhibit the properties of matter. But it would be virtually impossible for, say, a giraffe to appear in an information space not acted upon by natural selection. Another causal principle - *biological evolution* - would have to be invoked from this point on.

Today the Earth is embedded with artifacts like computer networks and circuses that cannot be accounted for by appeal to either the properties of matter or biological evolution. That is, biological evolution does not provide us with adequate explanatory power to account for the existence of computers any more than the properties of matter can explain the existence of giraffes. Computers are manifestations of yet another causal principle: *the evolution of culture*. Thus pattern in the structure and dynamics of information we encounter in the everyday world can be traced to three broad causal principles - the physical constraints and self-organizing properties of matter, biological evolution, and cultural evolution. This classification scheme, like all classification schemes, is somewhat arbitrary. There may be subclasses of these principles that deserve to be considered principles unto themselves [note 2], or one could argue that evolution is a self-organizing property of matter, albeit a spectacular one [note 3]. The point is: culture is the only process that has arisen since the origin of life that relentlessly exploits the combinatorial potential of information. Despite the fact that culture is grounded in biology (like biology is grounded in the physical constraints and self-organizing properties of matter), the probability of computers arising spontaneously in an information space not acted upon by cultural evolution (like the probability of giraffes arising spontaneously in an information space not acted upon by biological evolution) is vanishingly small. Thus it is inappropriate to dismiss culture as a predictable extension of biological evolution. It is qualitatively different from anything else biology has produced.

Since the machinery that renders cultural evolution - the human brain - is a product of biological evolution, much of what is 'out there' cannot be cleanly traced to a biological or cultural origin. We will discuss how biology constrains culture through the preferential spread of memes that satisfy biologically-derived needs. It goes the other way too; culture not only affects biological fitness through its effect on behavior (a phenomenon known as the Baldwin Effect) but it dramatically modifies the biological world. Some of the ways in which biological information gets tainted with cultural information seem relatively inconsequential, such as the trimming of hedges, whereas others, such as dog-breeding, have a long-lasting effect. (In fact, one could view dogs as the consequence of a memetic trajectory that was launched by the need to protect property.) Nevertheless, much as it is not imperative to address the role of physical constraints like gravity in studies of, say, embryonic development or squirrel foraging behavior, much can be said about culture without addressing the role of biological constraints.

1.3 Taking the Meme-Evolving Apparatus Seriously

The most salient shortcoming of existing models of cultural evolution, and quite possibly the reason they have had relatively little impact, is that although they tell us much about the transmission or characteristics of 'catchy' memes, they fail to adequately address the issue of how novelty is generated. To be of significant theoretical or predictive value memetics must give serious consideration to the processes by which experience in the world turns into new memes in our brains, and address how memetic novelty is expanded further through creative processes. Studies of creativity, on the other hand, have focused on the *individual*, obscuring the fact that creativity is a collective affair e.g. (Lenat [54], Schank & Leake [82], Mitchell [67], Boden [6]). The ideas and inventions an individual produces build on the ideas and inventions of others (the ratchet effect). Which memes spread and which ones die off reflects the dynamics of the entire society of individuals hosting them.

Thus although at a sufficiently abstract level the notion that culture evolves is obvious, we lack a theoretical framework that bridges transmission studies with studies of creativity, and spells out explicitly how the concept of evolution maps on to the case of culture. To accomplish this we need more than a quick and dirty list of what makes a meme 'catchy'; we have to consider the extent to which it resonates with and enriches the complex web of assumptions, beliefs, motives, and attitudes of its host - no simple matter. In short, we have to take the meme-evolving apparatus very seriously.

2 Meme: the Unit of Information that Evolves Through Culture

Because the concept of the individual is so germane to the human experience we have an anthropocentric tendency to assume that the individual is the appropriate basic unit of analysis. This tendency is probably exacerbated by the fact that in biology the individual *is* the object of the relevant evolutionary process (or more specifically the phenotypic expression of the information undergoing evolution). The memetic approach involves relinquishing our focus on the individual, and concentrating instead on the meme as the object of a second evolutionary process that makes cognition possible. This perspective can feel unnatural and disorienting but it discloses population-level phenomena that would otherwise go unnoticed because they are not readily detected through introspection.

2.1 The Distinction between a Meme and its Phenotypic Implementation

Durham [22] defines a meme as "any kind, amount, and configuration of information in culture that shows both variation and coherent transmission." Problems with this definition arise because it does not distinguish between cultural information as mental representation and cultural information as implemented behavior or artifact.

The genotype-phenotype distinction is useful here. The cultural analog of a genotype is the mental representation of a meme, and the analog of a phenotype is its *implementation*, or the form it takes if it gets expressed or communicated, typically as action or vocalization. Implementation transforms a meme, incorporating syntactic features characteristic of the channel through which it is conveyed (Brooks [10]). Thus, for example, a dance step looks different with each individual who performs it.

2.2 The Interconnectedness of Memes

Biologists use the term 'allele' to capture the notion of alternative heritable versions of a gene, and Durham [22] accordingly adopted the term 'allomeme' to refer to alternative versions of a meme. This basic concept was tailored to meet the constraints of biology; we all have the same number of genes, and two alleles of each gene (one from each parent). The cultural analog may be too clumsy to capture the subtle relationships between memes. Memes often appear to be stored in a distributed, network-like fashion, connected through webs of association (Hebb [32], Quillian [74], Pribram [73]) there is not necessarily a definitive rationale for saying where one stops and another begins, in semantic space let alone physical space. For example would we consider 'My mother looks good in blue' and 'My mother looks good under a blue umbrella' to be allomemes of the same meme, or different memes?

This kind of difficulty is circumvented by avoiding the notion of alternate versions altogether and using the term 'feature' to refer to a component of a meme. Thus related memes share features. In this paper, 'feature' can refer to a component with any degree of granularity below that of the meme in question; thus the scope of what might be considered a feature could range from an entire array of visual information depicting every perceived quality of a particular umbrella (such as might occur early on in perception) to one bit of information indicating the presence or absence of an umbrella (such as might occur at an advanced stage of cognitive processing). There can be nonlinear (epistatic) relations amongst the features of a meme, as well as between a meme and its implementation.

2.3 Meme as Pattern of Information Encoded in the Focus

In his book *Thought Contagion* [57], Aaron Lynch claims "Much as computer viruses make up a small fraction of computer software, so too do pernicious thought contagions form a small part of our mental software." But is this conservative approach necessary, or even sensible? Where do you draw the line between potentially culturally-transmittable memes and the rest of our "mental software"? The haiku-writer, for example, seems able to draw upon any sort of thought, memory, or imaginary construct. Therefore here we explore the opposite approach to that taken by Lynch; we bite the bullet and consider anything that can be the subject of an instant of experience, to be a meme. The category 'meme' now includes not only obviously transmittable ideas like 'Be good or you will go to Hell', but everything from a particular experience of vibrant 'redness', to a realization of a shorter route to work, to a feeling of dread associated with a teacher's posture or facial expression. This may strike some readers as outrageous, but it doesn't really make things as unwieldy as it might seem to at first glance. For the price of this added complication we gain a bridge that connects memetics with phenomena like perception, body language, planning, deductive reasoning, emotion, categorization, analogy... the stuff of the social and cognitive sciences. It may be our only viable direction. A theory of mind that can account for myth and freestyle dance, not to mention rapid personality assessment, is not easily achieved.

Our concept of meme can be clarified by invoking Kanerva's [42] notion of the *focus* - that part of the mind in which sensation (either external or internal e.g. hunger) and stored memory interact to produce a stream of experience. The states of the neurons that comprise the focus determine the content and experiential quality of an individual's awareness. One can think of a meme as a pattern of information that is or has been encoded in an individual's focus. It can be subjectively experienced as a sensation, idea, attitude, emotion, or combination of these, and it can direct implementation by the motor apparatus.

2.4 Chunking and Categorization of Memes

Frequently many memes get integrated into one through a process referred to in the psychological literature as 'chunking' (Miller [65]). Chunking involves forming associations amongst previously-learned memes and establishing this constellation of associations as a new meme in long term memory; it is analogous to the formation of co-adapted genes, or *schemata* (Holland [36]). Whereas chunking generally refers to the binding of semantically unrelated memes (as in the memorization of an arbitrary string of numbers), categorization involves the recognition of semantic relationships. Categorization and the resultant hierarchical structure of

knowledge will not be addressed here in any depth, though it is of relevance to point out that it seems reasonable to expect that the more extensively memes have been chunked or categorized, the greater the complexity of what can be held in the focus at once. Thus what constitutes a meme (and thus a feature) will differ amongst individuals, and within an individual over time.

2.5 Core, Enabler, and Hitchhiker Features

A first step toward a 'science of memetics' is to decompose memes into features or feature schemata according to how they relate to fitness. Here we will distinguish the following categories: (1) *core features* that contribute directly to the fitness of a meme, (2) *enabler features*, that enable or facilitate the implementation of core features, and (3) *hitchhiker features*, which exist in the meme due to arbitrary or accidental historical associations to features of the first two kinds. Core features tend to convey semantic information, and enabler features syntactic information, though one can think of situations in which some semantic information serves simply to facilitate expression of other semantic information i.e. functions as an enabler. The first two categories are vaguely analogous to the categorization of genes as structural or regulatory, and the last category is inspired by the phenomenon of genetic hitchhiking (Kojima & Schaeffer [51], Maynard Smith & Haigh [62], Kaplan, Hudson & Langley [43]). The closer together genes are on a chromosome the less likely they will be separated by crossover, so the more tightly linked they are said to be. Hitchhiker alleles confer no fitness advantage, but endure because they are linked to alleles that are important for survival. In both genetic hitchhiking and its cultural analog there is indirect selection for useless (or even detrimental) patterns through their association with beneficial ones. The concept of hitchhiking is closely related to that of exaptation - the evolution of organs or traits not evolved through natural selection for their current use (Gould [29]).

3 Selection and the Memetic Fitness Landscape

The next few sections examine in some detail how each of the three phases of evolution - selection, variation, and transmission - map onto the case of culture. Though these phases are discussed one at a time, it is worthwhile to keep in mind that in culture they are less spatiotemporally distinct than in biology. Selection can be coupled to either the generation of variation, or replication, or all three can occur simultaneously (for example when paraphrasing).

3.1 Memes 'Rely On' Brains to Select, Vary and Replicate Them

Von Neumann [91] postulated that any self-replicating system consists of two parts: (1) *uninterpreted information* - a self-description that is passively copied to offspring, and (2) *interpreted information* - instructions for how to construct offspring. This turned out to be true of the genetic code; there are genes that provide instructions to the body for how to sustain itself, and genes that provide instructions for how, with the help of someone of the opposite sex, to create a child. But unlike genes, memes do not come prepackaged with instructions for their reproduction. They rely on the pattern-evolving machinery of their hosts' brains to create, select, and replicate them. Since we preferentially spread ideas that satisfy needs, our needs define viable niches for memes to evolve toward. As infants we might cry and kick no matter what need is most pressing, but as children we acquire and continually refine a repertoire of memes that,

when implemented, satisfy various needs. We learn that reaching into the cookie jar satisfies one need, shouting 'help' satisfies another, et cetera. Our memes, and the behavior they elicit, slide into need-defined attractors (regions of stability) in the memetic fitness landscape.

The fact that memes are not independently self-replicating does not prevent them from achieving reproductive success. In fact it may ironically work in their favor, because the cognitive machinery they depend upon not only actively manipulates them to produce 'offspring-memes', but organizes them into a model of the world, or worldview, which it can use to figure out what to do whenever a situation is too complicated for its hardwired instincts. The worldview orchestrates behavior such that a meme gets implemented right when it is likely to be useful, and that increases the probability that other hosts will consider it worthy of replication. This also means that there is a continuous co-evolutionary interplay between pattern and landscape, which contributes to the oft-noted rapidity with which culture evolves.

3.2 Brains Select Memes that Satisfy Biological and Cultural Needs

Since many of our needs have a biological basis - e.g. the need for food, shelter, et cetera - meme generation is largely constrained by our heritage as products of biological evolution. Thus the topology of the memetic fitness landscape largely echoes that of the biological fitness landscape. In the short term, the biological fitness landscape, and thus the memetic fitness landscape, fluctuates continuously as one need is satisfied and others take precedence (Hull [41], McFarland & Sibly [64], Gabora & Colgan [24], Maes [59]). For example, after eating, ideas that pertain to finding food are less likely. However over the lifetime of an individual the set of biologically-based needs remains relatively constant. The trajectory of survival-motivated thought can be described as a limit cycle (periodic attractor) that moves through the set of stable memes whose implementations satisfy the various biological needs.

Variation-inducing operations restructure conceptual space and thus affect the memetic fitness landscape. Much as the evolution of rabbits created ecological niches for species that eat them and parasitize them, the invention of cars created cultural niches for gas stations, seat belts, and garage door openers. As one progresses from infancy to maturity, and simple needs give way to increasingly complex needs, the stream of thought acquires the properties of a chaotic or strange attractor, which can be viewed as the formation of crevices in the original limit cycle. The landscape is fractal (i.e. there is statistical similarity under change of scale) in that the satisfaction of one need creates other needs - every crevice when examined closely reveals more crevices. This is analogous to the fractal distributions of species and vegetation patterns described by ecologists (Mandelbrot [60], Palmer [69], Scheuring & Riedi [83]). An endpoint of a cultural evolution trajectory turns out to be not just a point in multidimensional space, but a set of points with their own fitness metric - a 'micro-landscape' in its own right. So although the memetic fitness landscape *loosely* follows the biological fitness landscape, there are places where it deviates, and this effect undoubtedly becomes more pronounced throughout an individual's lifetime. This means that the potential for meme diversity, though constrained by host need, is open-ended.

3.3 Personal versus Societal Worldviews

Our worldviews overlap to the extent that similar experiences and genetic make-ups cause our brains to store the same memes and styles of computation. But they don't overlap perfectly. Each host's train of thought traces out a unique trajectory through conceptual space. It can be useful to think in terms of not only the worldview of an individual, but also the worldview of a group or even human society at large, wherein all frontiers of human endeavor are incorporated.

3.4 The Landscape is Sculpted by the Need for Worldview Cohesion

A need that seems to surface to the forefront (have a large impact on the focus) when other needs are not pressing is the need to connect fragmented representations of the world into a logically-consistent worldview. Since our ability to make predictions and evaluate possible plans of action hangs on the accuracy of this worldview, the survival value of such a tendency is clear.

McCulloch and Pitts [63] showed that networks made of neuron-like components that perform the logical operations AND, OR, and NOT are theoretically capable of computing any Turing machine-computable function. In connectionist-type systems, logical relations are represented implicitly as constraints on the possible states of a system, and computation proceeds through settling into a solution that satisfies many constraints, rather than then explicitly calculating a solution. This is accomplished through modification of the associative strengths amongst the components of the system, and the process is referred to as relaxation or simulated annealing.

3.5 Hard-wired Selection

To the extent that the memetic fitness landscape echoes the shape of the biological fitness landscape, to which we have been adapting since life began, cultural selection is built right into our architecture. Our perceptual and cognitive systems are wired up such that they are primed to focus on and highlight those aspects of external reality that are relevant to our survival (or were in the past). The mental representations we form reflect that bias e.g. (Hubel & Wiesel [39], Marr [61]). Second, the associative organization of memory constrains variation-generating operations. So selection is built right into our hardware.

3.6 Malleable Forms of Selection

In order to create, or even just understand, a new meme, there has to be a conceptual framework from within which it will make sense, and a need, or niche, for it. Therefore, any relevant precursor or "*proto-memes*" must first be assimilated (Wallas [93]). This constraint amounts to a malleable, or plastic, form of selection on new memes.

When one host exhibits a meme that another observing host values, the observing host often displays reinforcing body language and emits words of encouragement. Likewise, if the meme is threatening or inconsistent with valued memes, the observing host's words and behavior tend to be discouraging. Our need for social acceptance makes us more likely to exhibit memes that have been reinforced and less likely to exhibit those that have been discouraged. From a meme's-eye perspective this looks like a subtle strategy by which a meme in one host selectively shapes the probability of its implementation in other hosts.

Selection can also occur after a representation has been internalized but prior to being phenotypically expressed. For example, *mentally simulating* what would happen if an idea were implemented can weed out unworthy ideas (Nersessian [68]). The success of mental simulation varies with the accuracy of one's internalized model of the world, but it provides at least a rudimentary form of selection.

Finally, selection can operate through *biased transmission*; that is we choose to imitate certain individuals and not others (Boyd & Richerson [9]).

4 Creativity: the Source of Cultural Variation

4.1 Strategy Guides Trajectories through the Memetic Fitness Landscape

The existence of an open niche does not guarantee that the niche will ever be found. In biology the process by which this happens is largely random. Though most mutations and recombinations are detrimental, so many variants are generated that it is not necessary to be clever about *how* they are generated. We could say that biological evolution is a more breadth-first search algorithm than cultural evolution because it relies primarily on massive parallelism rather than strategy.

In culture, on the other hand, variants are generated strategically. We could say that cultural evolution is a more depth-first approach to searching a space of possibilities. The trajectory of a stream of thought is constrained by connections between representations that are similar or spatiotemporally related (Schank [81]), which increases the probability that an advantageous variant is found. For example, when considering the problem of having to get out of your car every day to open the garage door, you would not think about doilies or existentialism, but concepts related to the problem - electricity, human laziness, and various openers you have encountered before. If you were to spend several months on this problem, ideas that pertain to openers of various kinds would for you become a highly active region of conceptual space, analogous to the uncharacteristically high level of activity (and polymorphism) in a small portion of the human genome known as the major histocompatibility complex (MHC) which deals with immune response (Hughes & Nei [40]). During creative thought, memes potentially relevant to a solution would evoke or activate one another, altering or strategically (though not necessarily consciously) manipulating them, a process that is said to involve pattern completion, constraint satisfaction (Rumelhart & McClelland [80]), and the tweaking, blending, redescription, abstraction, and recoding of representations (Hofstadter [34], Holland &c. [37], Karmiloff-Smith [44], [46], Ram [75], Clark & Thornton [14]). Neurophysiological evidence suggests that creating new contexts for representations, that is manipulating them, involves hippocampal binding or linking (Squire [88]), and synchronization (Klimesch [49]), of features encoded by distributed cortical cell assemblies.

To sum up: fueled by need and constrained by association we carve out trajectories through meme space, and because the fitness landscape that guides this process is fractal, every time that landscape steers the production of a new meme (or even just a slight variant of a preceding meme), the new meme in turn redefines the landscape, and so on, recursively.

4.2 Sparse Distributed Memory as a Platform for Generating Variation

SPARSE, DISTRIBUTED MEMORY (Kanerva [42]), or SDM, is a mathematical model of the mechanics underlying the storage and retrieval of memories. It was motivated by the desire to understand how memory provides conscious experience with a thread of continuity via the spontaneous sequential activation of concepts or experiences that are related to one another, sometimes superficially, and other times through resemblances that are highly abstract or metaphorical.

Kanerva draws an analogy between the focus and a combined address-datum register in a computer; they both contain data and serve as a pointer to memory, and can both read from and write to memory. An instant of experience is encoded in the focus by a high-dimensional vector of difference relations, or bits, that represent the presence or absence of some feature, and the mathematics generalizes such that a pattern of bits can represent a value along some dimension. The Hamming distance between two memes is the number of bits that differ. (So the Hamming distance between 11111 and 11100 is two.) Since each meme has an antipode (for example, the antipode of 11111 is 00000), the space of all possible memes can be visualized as a sphere. The address of a meme is the information pattern that specifies where the meme is stored.

If L is the number of possible features in a meme, the number of possible memes is 2^L . Assuming L is large the size this space is enormous, so the memory is sparse in that it stores only a small fraction of the set of all possible memes. For example, to construct a SDM with $L=1,000$, then out of the possible addresses, a workable number of them, say 1,000,000, are chosen at random to be actual storage locations. The number of memes at Hamming distance k away from any given meme is equal to the binomial coefficient of L and k , which is well approximated by a Gaussian or normal curve. If meme X is 111...1 and its antipode 000...0, and we consider meme X and its antipode to be the 'poles' of the hypersphere, then approximately 68% of the other memes lie within one standard deviation () of the 'equator' region between these two extremes (figure 1). As we move through Hamming space away from the equator toward either Meme X or its antipode, the probability of encountering a meme falls off sharply by the proportion . In our example, the median distance from one location to another is 424 bits, and 99.8% of stored memes lie between 451 and 549 bits of any given location.

Figure 1: Schematic distribution of Hamming distances between addresses of meme X and addresses of storage locations

A computer reads from memory by simply looking at the address in the address register and retrieving the item at the location specified by that address. The sparseness of the SDM prohibits

this kind of one-to-one correspondence, but it has two tricks up its sleeve for getting around this problem.

First, it feigns content addressability, as follows. The particular pattern of 1s and 0s that constitutes a meme causes some of the synapses leading out from the focus to be excited and others to be inhibited. The locations where memes get stored are memory neurons, and the address of a neuron amounts to the pattern of excitatory and inhibitory synapses from focus to memory that make that neuron fire. Activation of a memory neuron causes the meme to get written into it. Thus there is a systematic relationship between the memes' information content and the locations they activate.

Second, since the probability that the ideal address for storing a meme corresponds to an actual location in memory is vanishingly small, storage of the meme is *distributed* across those locations whose addresses lie within a sphere (or more accurately, hypersphere) of possible addresses surrounding the ideal address (figure 2). The radius (in Hamming metric) of this sphere is determined by the neuron activation threshold. Each location participates in the storage of many memes. In this example we assume that 10,000 memes have been stored in memory. Each meme is stored in 1,000 (of the 1,000,000 possible) locations, so there are approximately 10 memes per location. The storage process works by updating each of the L counters in each location; to store a 1 the counter is incremented by 1, and to store a 0 it is decremented by 1. These nearly one million operations occur in parallel.

Figure 2: Meme X is stored in all locations within hypersphere of radius k surrounding its ideal address

If after a meme, say meme X , is stored, the individual's attention is directed toward external stimuli, then nothing is retrieved from memory. But to the extent that memory contributes to the next instant of awareness, the storage of X activates retrieval of not only X itself but all the other memes that have been stored in the same locations. The next meme to be encoded in the focus, Y , is found by determining the best match; that is, by averaging the contributions of all retrieved

memes feature-by-feature. Whereas the 1,000 retrieved copies of X (and memes similar to X) reinforce one another, the roughly 10,000 other retrieved memes are statistically likely to cancel one another out, so that ends up being similar to X . Though is a reconstructed blend of many memes it can still be said to have been retrieved from memory. can now be used to address the memory, and this process can be reiterated until it converges on meme Y that satisfies a current need. This is how the SDM accomplishes depth-first search. The closer Y is to X , the faster the convergence. In our example, assuming $r=425$, if X and Y are more than 200 bits apart Y is unlikely to be retrieved, but if they are 170 bits apart Y will be retrieved in about four iterations. Keeler [48] has shown that SDM is a superset of Hopfield-type and connectionist models of autoassociative or heteroassociative memory. The SDM formulation is used here because it lends itself to an understanding of the mechanics of phenomena we are interested in. Since the dynamics emerges from the statistics, rather than from a central executive, it can cope with creative and seemingly unmechanical cognitive phenomena such as wordplay or slips of the tongue. Moreover it is ideally suited to handle the problem of sequential access, which will become relevant when we look at how an infant establishes a train of thought. To model the recollection of a sequence, meme X is simply used as the address to write Y , Y as the address to write Z , and so on. Working memory can be viewed as the memes that lie within a given Hamming distance of the meme in the focus such that they are retrievable within a certain number of iterations. Categorization could involve the identification of a feature pattern, and readdressing memes that contain this pattern so that their new addresses put them within working memory reach of one another. Kanerva shows that the architecture of common neural components and circuits in the brain are ideally suited to implement a SDM.

In SDM, associations between memes are not explicitly represented as connection strengths but as proximity in multidimensional space. However in the end they amount to the same thing. The smaller the Hamming distance between two memes, the higher the probability that they will be retrieved simultaneously and blended together in the focus (or one after the other in a chain of related thoughts). What allows the memes to be retrieved simultaneously, however, is that they are either stored in the same neurons or in neurons with nearby addresses, which in turn reflects the neurons' connectivity. Thus factors that affect the storage of a meme will also affect retrieval of that meme; the two processes are intimately connected.

5 The Replication and Transmission of Memes

The memetic approach to cognition is not incompatible with approaches that stress the role of innate mechanisms e.g. (Pinker [70]). Rather, as Lumsden & Wilson [56] point out, it builds on this framework, adding that the study of cognition will flounder until we admit that the role of transmission is equally undeniable. Transmission links the memetic processing within an individual to not only memetic processing in other directly-encountered individuals, but processing in individuals *they* encounter, and so on. The ideas and inventions any one individual produces build on the ideas and inventions of others. This phenomenon is known as the *ratchet effect*, and its impact is demonstrated in the following example. If you were suddenly dropped into the Australian desert, you probably would not survive for long. However if you were to run into an aborigine who grew up learning desert survival skills from her family and community that had been passed on and improved upon for generations (such as how to find water in obscure places) you might survive for some time [note 4].

5.1 Intra-Individual Meme Replication via Implicit Pointers to Memory

We saw how, unlike genetic material, memes do not contain instructions for how to make copies of themselves; they replicate when their hosts teach or imitate one another. The memes in a SDM-like memory, however, have a self-replication capacity in the following sense. The pattern of information that constitutes a meme determines which of the synapses leading out from the focus are excited, and which are inhibited - it determines how activation flows through the memory network - which in turn determines the neurons where the meme is stored and from which the next meme is retrieved. Thus embedded in the neural environment that supports their replication, memes act as implicit pointers to memory. These pointers prompt the dynamic reconstruction of the next meme to be subjectively experienced, which is a variation of (statistically similar to) the one that prompted it. It is in that sense that they self-replicate.

5.2 Transmission is Lamarckian and Phenotypically Mediated

Internal replication (with variation) makes cultural transmission Lamarckian - modifications acquired since the acquisition of a meme can be passed on to others (Dawkins [17]). The related point that transmission is phenotypically mediated, as Dennett [19] points out, makes a "science of memetics" less daunting. It means that, unlike biologists, we don't have to fully understand the nature of mental representation to study transmission.

5.3 Any Experience can Affect Transmission

While biological needs affect the focus from the inside, environmental stimuli impact it from the outside. The information-based orientation supports a broader conceptualization of the transmission process than is generally taken. For the purpose of understanding the evolutionary mechanics underlying culture, any interaction between an organism and its environment that impacts the focus is part of this process. It often occurs through imitation of conspecifics (Smith [86], Bonner [7], Robert [77]), or guided instruction (Vygotsky [92], Tomasello &c. [90]). but not necessarily. For example, does it matter whether a child learns to peel a banana by watching her mother, or a monkey, or a cartoon character on TV? What matters is that the child has a mental representation of how to peel a banana. All kinds of interaction with the environment provide us with new representations or alter existing ones, and therefore have the potential to affect the interplay of ideas and emotions that are culturally transmitted.

5.4 Transmission Studies in the Social Sciences

Steps toward an evolutionary perspective on cultural transmission have been taken in the social sciences. This research falls under various names: social diffusion e.g. (Rogers [79]), social epidemics e.g. (Mackintosh & Stewart [58]), coevolution (Durham [22]), social learning e.g. (Tomasello &c. [90]), and social contagion (Rodgers & Rowe [78]). There has also been work done on group creativity e.g. (Cziksztentmihalyi [15]).

The evolutionary context could be made much more explicit in this work, capitalizing on what we have learned about evolution in the biological realm by looking for phenomena such as epistasis and drift (random statistical bias due to sampling error) (Wright [96], Cavalli-Sforza &

Feldman [12]) or by viewing reciprocal interactions between like-minded individuals as a cultural analog of biological altruism. It may be through ongoing reciprocal interactions of this kind that a memetically-derived social structure emerges, wherein individuals who regularly generate pleasurable or powerful memes come to be observed carefully and imitated frequently, while other individuals are ignored. These outcasts may be excluded from memetic exchange and come to exhibit a cultural version of the Founder Effect (Holgate [35]) - reduced variation due to drift.

Our knowledge of biological speciation could be applied to study individuation and division of labor in a family or society. In both cases small differences are amplified through positive feedback leading to transformation of the space of viable niches for the evolution of information patterns. This approach could help us address questions such as why siblings are often so different from one another.

6 A Scenario for the Origin of Cultural Evolution

We have discussed how memes evolve through selection, variation, replication and transmission. We now address the issue of how cultural evolution got started in the first place.

6.1 The Origin of Life and its Cultural Analog

The origin of life poses the following paradox: how could something as complex as a self-replicating molecule arise spontaneously? Traditional attempts to explain this entail the synchronization of a large number of vastly-improbable events. Proponents argue that the improbability of the mechanism they propose does not invalidate it because it only had to happen once; as soon as there was *one* self-replicating molecule, the rest could be copied from this template. However Kauffman [47] proposes an alternative scenario that does not entail the synchronization of numerous improbable events. He suggests that life arose through the self-organization of a set of autocatalytic polymers. When catalytic polymers interact with one another their average length increases. As their length increases, the number of reactions by which polymers can interconvert increases faster than the number of polymers. Therefore a set of interacting molecules under conditions such as are likely to have existed at the time life began would inevitably reach a critical point where there is a catalytic pathway to every polymer present. Jointly they form a self-reproducing metabolism.

We now ask: What is the cultural analog to the origin of life? One could say it is the point in history when organisms acquired the capacity for social transmission, but as many authors e.g. (Darwin [16], Plotkin [71]) have pointed out, although transmission is wide-spread throughout the animal kingdom, no other species has anything remotely approaching the complexity of human culture. Donald [20] argues convincingly that the bottleneck in cultural evolution is the capacity for innovation. Innovation requires more than a kind of awareness that integrates survival needs with environmental affordances, and draws upon memory only to interpret stimuli, or consult a mental map, or recall how some drive was satisfied in the past. It requires an ongoing train of creative representational redescription and counterfactual 'what if...' type thinking. This suggests that the cultural analog to the origin of life was the origin of the first self-perpetuated, potentially-creative stream of thought in an individual's brain.

When an infant has its first experience, there is nothing in memory to draw upon to contribute to that experience; the first meme to occupy its focus does not remind it of anything. Therefore experience is initially driven only by external or internal stimuli, not by memory. Thus the evolution of culture poses a paradox analogous to that of the origin of the self-replicating molecule - how does an infant develop the capacity for a self-sustained train of thought that creatively integrates new experiences with previous ones? Consistent with Kauffman's assertion that the bootstrapping of an evolutionary process is not an inherently improbable event, the "it only had to happen once" argument does not hold water here because the cultural analog to the origin of life takes place in the brain of every infant.

6.2 Establishing an Autocatalytic Set of Sparse, Distributed Memories

This section outlines how a SDM-like stream of thought might get established. Let us say that the first meme to occupy an infant's focus and then get stored in memory is a visual experience of its mother in a blue coat. The next is the sound of a dog barking. The Hamming distance between these memes exceeds the maximum for one meme to evoke the memory of another, so the barking does not remind the infant of its mother. Later the infant sees its mother in a red coat. This meme evokes or 'catalyzes' the memory of its mother in a blue coat. To avoid getting stuck in an endless loop wherein 'mother in blue coat' then evokes 'mother in red coat' et cetera, it may form the category 'mother'. However *that* meme does not remind it of anything, so this stream of thought dies off quickly.

As the infant accumulates memes, the statistical probability that a meme in the focus will activate a meme from storage increases, so the streams of reminders get longer. Eventually the memory becomes so densely packed that any meme that comes to occupy the focus is bound to be close enough in Hamming distance to *some* previously-stored meme(s) to activate a variant of itself. This marks a phase transition to a state in which, just as with the origin of life, the sequential activation of self-similar patterns is self-propelled; the memes now form an autocatalytic set. The focus is no longer just a spot for coordinating stimuli with action, but a forum for the variation-producing operations that emerge naturally through the dynamics of iterative retrieval. The resultant memes evolve along different trajectories toward different basins of attraction, 'specializing' in the fulfillment of one need or another. Those that satisfy the same need compete until one becomes habitual, while those that fulfill different needs are able to coexist within the same host. As with biological speciation, small differences are amplified through positive feedback leading to transformation of the space of viable niches for the evolution of information patterns.

Note that in this example the 'mother' meme is the infant's first category. A simple way of describing this situation is: if the 'mother in blue coat' meme is represented as 111, and the 'mother in red coat' meme is represented as 110, the 'mother' meme can be represented as 11*, where * means either 1 or 0. It is also the infant's first *derived* meme. That is, it is the first information pattern to enter the focus not purely by way of external stimuli but through the necessity of a logical operation on previously-stored memes - in this case an OR gate - which could be realized in the brain via adjustment of connection strengths. The act of categorization projects the original information space, which had n relevant dimensions, onto a new space that has $n-1$ dimensions (for example, here coat color is no longer relevant). It effectively makes the

space denser, and increases susceptibility to the autocatalytic state. On the other hand, creating new memes by combining previously-stored memes could interfere with the establishment of a sustained stream of thought by increasing the dimensionality of the space, thereby decreasing density. If indeed cross-category blending disrupts conceptual autocatalysis, one might expect it to be less evident in young children than in older children, and this expectation is born out experimentally (Karmiloff-Smith [45]).

Note also that the density of memes necessary to reach and maintain this autocatalytic state will depend on the neuron activation threshold. If the threshold is too high (the hypersphere of potentially activated memes is too small) even very similar memes cannot evoke one another, so a stream of reminders, if it happens at all, dies off readily. If the threshold is too low (the hypersphere too large), then any meme will evoke a multitude of others not necessarily meaningfully related to it. Successive patterns in the focus will have little or no resemblance to one another; the system may be catalytic but it is not autocatalytic. The free-association of the schizophrenic (see Weisberg [95]) seems to correspond to what one might expect of a system like this. For memory to produce a steady stream of meaningfully-related yet potentially creative reminders, the threshold must fall within a narrow intermediate range. This is consistent with Langton's [53] finding that the information-carrying capacity of a system is maximized when its interconnectedness falls within a narrow regime between order and chaos. The situation may turn out to be slightly more complicated; sustaining a creative train of thought may involve not only keeping the activation threshold within a narrowly-prescribed range but dynamically tuning it in response to the situation at hand. This is particularly likely if the memory is not uniformly dense (i.e. clusters of highly-correlated memes) or if different kinds or stages of thought require different degrees of conceptual blending. For example, finding unusual associations, such as puns that employ epistatic relationships between semantic and syntactic components of a meme, may depend on the preconscious ability to voluntarily increase hypersphere radius. Refinement of the pun may then require a decrease in radius.

Thus we have a plausible scenario for how cultural evolution, like biological evolution, could have originated in a phase transition to a self-organized web of catalytic relations between patterns.

7 Why is Culture Unique to Humans? - A Speculative Answer

Recall that in order for a network of memes to reach an autocatalytic state, the activation threshold must be calibrated to fall within a narrow range to achieve a delicate balance between the capacity for semantic continuity on the one hand and creative association on the other. The penalty for having too low a threshold would be very high; successive thoughts would not necessarily be meaningfully related to one another, and thinking would be so muddy that survival tasks are not accomplished. Too high a threshold, on the other hand, would not be life-threatening. The focus would virtually always be impacted with external stimuli or internal drives such as hunger; memory would be pretty much reserved for recalling how some goal was accomplished in the past. A stream of experience that involved the iterative reorganization of stored memes would likely die out before it produced something creative. This may be the situation present in most brains on this planet, and the reason that apes are limited to episodic memory e.g. (Donald [20]).

The advantages of a sustained train of thought would be largely lost on animals because they have neither the vocal apparatus nor the manual dexterity and freedom of upper limbs to *implement* complex ideas. No matter how brilliant their thoughts were it would be difficult to do something useful with them. Moreover, in an evolutionary line there is individual variation, so the lower the average activation threshold, the higher the fraction of individuals for which it is so low that they do not survive. It seems reasonable to suggest that apes are not *a priori* prohibited from evolving complex cognition, but that there is insufficient evolutionary pressure to tinker with the activation threshold until it achieves the requisite delicate balance to sustain a stream of thought, or to establish and refine the necessary feedback mechanisms to dynamically tune it to match to the degree of conceptual fluidity needed at any given instant. It may be that humans are the only species for which the benefits of this tinkering process have outweighed the risks.

8 Computational Approaches to Cultural Evolution

Meme and Variations, or MAV (Gabora [25]) is a computer model of a society composed of interacting neural network-based agents. Unlike other such models that combine biological and cultural evolution e.g. (Ackley [2], Spector & Luke [87]) these agents don't have genomes, and neither die nor have offspring, but they can invent, implement, and imitate memes. MAV successfully evolves patterns of information through cultural implementations of variation, selection, and replication, and exhibits phenomena observed in biological evolution such as: (1) drift (2) epistasis increases time to reach equilibrium, (3) increasing frequency of variation-generating operations increases diversity, and (4) although in the absence of variation-generating operations meme evolution does not occur, increasing variation-generation much beyond the minimum necessary for evolution causes average fitness to *decrease*. MAV also addresses issues specific to cultural evolution, such as the effects of mental simulation, imitation, and strategy. Perhaps the most interesting finding it yielded was that although for the society as a whole the optimal creation-to-imitation ratio was approximately 2:1, for the agent with the fittest memes, the less it imitated (i.e. the more computational effort reserved for creation) the better.

MAV will hopefully serve as a stepping stone to more advanced models of memetic evolution. Of particular interest will be models that: (1) like Tierra, a model of biological evolution (Ray [76]), harness the power of evolution to explore and transform an *open-ended* space of possible patterns, but (2) explore the space strategically on the basis of accumulated knowledge rather than at random [note 5], (3) have fitness landscapes that emerge through the needs of the agents within the constraints of their environment as in (Maes [59]), and (4) have agents that must learn for themselves which memes, when implemented, best satisfy each of their various needs.

Mathematical models of culture are too minimal to cope with the open-ended diversity of culturally-derived information (variation is generally restricted to trial and error learning or transmission error) l&c.one address the numerous intra-individual factors that undoubtedly have emergent inter-individual consequences, such as how representations are grounded in experience and how they are stored, retrieved, and implemented. Models of individual intelligence and creativity, on the other hand, lack transmission and replication. Although this research may not explicitly attempt to address group processes it typically focuses not on the sorts of simple inferences and creative acts that a person raised alone in the wild would be capable of, but on

complex acts such as story comprehension, that might be unlikely to develop in isolation. With the advent of massively parallel computers it is becoming increasingly feasible to place computational models of individual creativity and problem-solving in a cultural context. This approach could provide insight into not only problems pertaining to representation and culture, but evolution in general, through comparison with biology. For example, the question of why there is so much redundancy in the genetic code has generated much discussion which may also apply to the question of why there are redundant mental maps in the brain; both may reflect constraints on the nature of an information-evolving code.

9 A Memetic Perspective on Induction, Censors, and the Unconscious

We turn now to how the cultural evolution perspective can shed light on some aspects of how people think and interact.

9.1 Mental Censorship and Induction

Initially an infant is unselective about meme acquisition, since (1) it doesn't know much about the world yet, so it has no basis for choosing, and (2) its parents have lived long enough to reproduce, so they must be doing something right. However just as importing foreign plants can bring ecological disaster, acquisition of a foreign meme can disrupt the established network of relationships amongst existing memes. Therefore the infant develops mental censors that ward off internalization of potentially disruptive memes. Censors might also be erected when a meme is found to be embarrassing or disturbing or threatening to the self-image (Minsky [66]). In a SDM-type architecture this could be accomplished by increasing the activation threshold so as to prematurely terminate the relaxation process and prevent the content of the focus from assimilating with stored memes. Much as erecting a fence increases the probability that people will stay on either one side or the other, this would warp the statistical probabilities involved in this meme's partaking in the ongoing process of associative recall, such that the individual either avoids the censored meme or dwells on it excessively. This seems to be consistent with our bipolar attitude toward highly censored subjects such as aggression and sexuality.

On the other hand, when the cost of the disruption is outweighed by the potential benefit accrued by a world model that can accommodate the new meme, the threshold would be lowered. Most thoughts seem to have little effect on our understanding of the world at large, but once in a while we experience a meme that significantly modifies our world view. The situation is reminiscent of superconductivity; lowered resistance increases correlation distance, and thus a perturbation to any one pattern can percolate through the system and affect even distantly-related patterns. It would be interesting to determine experimentally whether the "inductiveness" of our memes, like other self-organizing systems, exhibits the ubiquitous inverse power law (Bak, Tang & Wiesenfeld [3]). Just as in a sand pile perched at the proverbial Tedge of chaos' once in a while a collision between two grains will lead to another in just the right chain reaction to generate a large avalanche, occasionally one thought will trigger a chain reaction of others in a way that reconfigures the conceptual network.

9.2 The Unconscious

The concept of the unconscious has been influential and useful despite the obvious incongruity: how is it that we can consciously discuss something that is unconscious? What we may be referring to is the fleeting experience of memes that are dynamically reconstructed as in a SDM but which do not readily assimilate with other memes and so get discarded from the focus. In other words, the need for worldview consistency prohibits further computational resources from being spent on trying to integrate what appears to be a nonsensical construction into the memory. Of course there is no reason why a meme that is not immediately integrated into the memory might nevertheless affect the memory; the very process of determining whether it can be assimilated or not might itself have effects that infiltrate the system. This possibility is supported by the finding that subjects' behavior can be affected by priming material of which they have no recall e.g. (Dunbar & Schunn [21], Fehrer & Raab [23]). Subconscious processing of this sort could, in fact, resculpt the memetic fitness landscape in such a way that a previously-discarded meme is more readily assimilated the next time it is encountered.

9.3 Cultural Momentum

Despite being derived, directly or indirectly, from human need, memes do not always promote our survival (Greene [30], Alexander [1]). As Dawkins [18] points out, "It is true that the relative survival success of a meme will depend critically on the social and biological climate in which it finds itself, and this climate will certainly be influenced by the genetic make-up of the population. But it will also depend on the memes that are already numerous in the meme-pool." Much like runaway selection in biology, once a meme can replicate with variation on the basis of some selection criterion, it can evolve out of the orbit of the need that originated it. We can't *help* but engage in a stream of thought, spontaneously generating new memes like "if only such and such had been different...S, any more than biological evolution can help but generate new species. This *cultural momentum* could explain why, despite the intuition that individuals control their streams of thought, creators often express surprise at the sudden appearance of an idea, and deny active effort in its immediate creation (Bowers &c. [8], Guilford [31], Kubose &c. [52], Wallas [93]). We seem to control the birth of 'our' ideas only to the extent that we provide a fertile ground for them to be fruitful and multiply - by internalizing relevant background knowledge, identifying new needs, and exposing ourselves to stimuli that help trigger ideas that fulfill those needs. (So if you don't like this idea, don't blame me.)

Spurious basins of attraction sometimes arise in recurrent neural networks through the compositional interaction of explicitly-trained attractors (Hopfield [38]). Cultural momentum may boil down to a phenomenon of this sort. Just because the memetic fitness landscape largely echoes the biological fitness landscape, that doesn't mean that behavior elicited by memes in spurious basins of attraction arising through representational redescription need always be conducive to survival. Nevertheless a stream of thought could be censored before it elicits harmful behavior. Streams of thought probably get blocked or sidetracked on a regular basis, not just by censors, but by minute-to-minute undulations in the hyperdimensional fitness landscape, that is, change in the relative urgency of the multitude of survival-related or derived needs impacting the focus.

The concept of cultural momentum sheds light on the issue of free will. Those who argue for the existence of a central executive in memory may come to be viewed as the creationists of philosophy and cognitive science. Human will can instead be viewed as the emergent orchestration of needs, stimuli, and retrieved memories impacting the focus, which is subject to cultural momentum and therefore, in a sense, beyond our control.

9.4 The Birth of Creative Ideas

The biologically-inspired model developed here supports a variant of the combination theory of creativity - that new ideas arise through combinations and transformations of old ones (Boden [6], Koestler [50]). The aspect of this theory that does not ring true is that it neglects the role of emotions. Here we consider emotions, as well as ideas, to be encoded as information in memes; some components of a meme are simply interpreted by parts of the mind that experience them as emotion, whereas others are interpreted by parts of the mind that experience them as ideas. Much research on analogy deals with how the structure or 'conceptual skeleton' underlying one idea gets abstracted and applied to another (Gentner [26], Gick & Holyoak [27]). We can expand on this general idea by suggesting that many forms of creative expression begin with the (unvoiced) question: What would the pattern of information that encoded the emotion I experienced during *this* particular event look like if expressed through the constraints of *that* medium? The existence of inherent limitations on how a pattern could be translated from one domain to another is consistent with the frequent observation that creativity involves both freedom and aesthetic constraint. Thus all creativity is directly or indirectly derived from experience in the world, and since the mathematics underlying this world, the set of all natural functions, is a small subset of all *possible* functions, the constraints that guide creation are not arbitrary but objective and familiar; for example the drum beat of a song might echo a heartbeat, when the rhythm and chord progression are reminiscent of the sound of someone sobbing we feel sad, and we hear the wrong note even if we have never heard the song before.

It makes sense to expect that a meme or meme complex that has been censored (for example because it evoked unbearable sadness or anger) would be vulnerable to being targeted as an area where worldview cohesion could be increased. Since at the time the censored material was experienced it was prohibited from forming associations to obviously-related memes, it in turn cannot be *retrieved* through these expected or straightforward associations. It can only be retrieved via 'backdoor entrances', that is associations that reflect structural congruity at an abstract level. Thus a musician may come to habitually funnel patterns encountered in a variety of domains - and particularly censored material - through modules that filter out hitchhiker and enabler features, and adapt the core features (or feature schemata) to the constraints of music. It is in this repackaged format that memes originally deemed dangerous can be integrated into the memory at large without harm, and it is through this process that the creator establishes a sense of control over memes that were previously 'off-limits'.

9.5 Conceptual Linkage Disequilibrium and Hitchhiking

Arguments against a theory of cultural evolution generally consist of a series of statements as to how the cultural situation differs from that of biology e.g. (Gould [28], Thagard [89]). These arguments, however, do not constitute a viable reason to discard the idea that culture is an

evolutionary process. Imagine that 100 years before Darwin proposed the theory of biological evolution through natural selection, another scientist had discovered another system whereby patterns of information evolved, say in a test tube. Given this scenario would it have made sense for Darwin to dismiss the importance of biological evolution simply because it proceeds through different mechanisms from the originally-discovered test tube form of evolution? This would obviously have been foolish. It would have robbed humanity of not only the unifying power of a theory of biological evolution, but the opportunity to use knowledge of how evolution works under one set of constraints and affordances as a scaffold to direct the study of how it works under a different set of constraints and affordances. But time and again it is argued that a theory of cultural evolution is doomed simply because it would have to work through different mechanisms from those of biological evolution.

Ironically this situation in itself provides us with a nice example of how knowledge of evolution acquired in the realm of biology can help unravel analogous situations in the realm of culture. The biasing effect of historical association is an important theme in population genetics. Alleles of linked genes, such as those that code for red hair and freckles, continue to co-occur more often than chance even after individuals in the lineage from which these alleles originated begin mating randomly with individuals from other lineages that did not have these alleles. One can theoretically measure the number of generations necessary for these genes to achieve a state of random association or *linkage equilibrium*, and this process can be modeled computationally. Similarly, people often have difficulty applying an idea or problem-solving technique to situations other than the one in which it was originally encountered, and conversely, exposure to one problem-solving technique interferes with the ability to solve a problem using another technique e.g. (Luchins [55]). Psychologists refer to this as *mental set* (though it is more commonly known as 'throwing the baby out with the bathwater'). We could view mental set as a state of conceptual linkage *disequilibrium*. In the present example, conceptual linkage disequilibrium hinders our ability to abstract the basic concept of evolution from its biological manifestation so that it can be applied with ease to the case of culture. One could argue that it would make sense for cultural evolution to be the default form of evolution in disciplines outside of biology, much as in tropical climates the default form of skiing is water-skiing rather than snow-skiing.

Conceptual linkage equilibrium is achieved when all instances of hitchhiking have been obliterated. In an influential paper on the relationship between DNA polymorphism and recombination rates, Begun and Aquadro [5] suggested that genetic hitchhiking may have significant evolutionary impact:

"This correlation suggests that levels of neutral variation in many of the gene regions for which variation has been measured have been reduced by one or more hitchhiking events. Provided that a new selectively favored mutation goes to fixation before another advantageous mutation arises close to it, each fixation will be surrounded by a 'window' of reduced polymorphism, the relative size of which is proportional to the rate of recombination for that region of the genome." The general idea here translates nicely to cognition: if a meme goes to fixation in a society due to selective advantage conferred by one or more core features, its enabler and hitchhiker features will also exhibit reduced polymorphism, and the size of the 'window' will vary with the extent to which hitchhiker features are conceptually bound to that meme. (For example, the basic concept

of a typewriter/computer keyboard was historically enabled by the QWERTY keyboard design, which has now gone to fixation despite poor performance relative to other possible keyboard designs.) One could argue that recreation is the re-creation of information patterns in different domains from the ones in which they were originally encountered, thereby filtering out conceptual prejudices that reflect nothing more than mechanical constraints or historical legacies of the original domain. Play, intellectual pursuits, and other creative endeavors are then algorithms for achieving a state of conceptual linkage equilibrium through mental operations that, like genetic recombination, increase polymorphism by reducing fixation through hitchhiking.

The account of creativity proposed here may seem too simple to explain the seemingly limitless human potential for creativity, but it may seem less far-fetched when we consider the variety of species produced by biological evolution, which operates without the benefit of strategy. Furthermore, raw materials for the creative process may be acquired in exceedingly subtle ways. It is conceivable that you might watch a stream flow and without your consciously thinking, "It flows... things can flow... *I* could even, in some sense, adopt a more flowing approach to life", the experience might be reconfiguring your memetic infrastructure in a way that makes you more easygoing. I am not making any claims about the extent to which experiences of this sort affect us or even whether they occur at all, but rather suggesting that we not prematurely place a lid on the kinds of processes that could affect a network of representations and thereby affect creation and transmission.

10 Memetics as the Missing Link between Science, Spiritual Notions, and Feminism

Recall that to implement a meme is to express it, so that it crystallizes from the world of ideas into words or body language or objects in the physical world. Memes fool potential hosts into believing they want or need or identify with them by attaching themselves to supporting memes that we already identify with, or that represent things we need or want (as advertisers are well aware). Thus the greater the extent to which we identify with or value ourselves in terms of the memes (including those that pertain to the self) and implemented artifacts we possess or lack, the more vulnerable we are to ever-more-seductive forms of persuasion and advertising which tie up time, energy, and resources that could be applied toward other goals.

One way to defend oneself against painful or manipulative memes is to construct what Dennett [19] refers to as a 'meme-immunological system'; that is, formulate new memes specifically to deflect 'memetic antigens'. However constructing 'memetic antibodies' of this sort is time-consuming, and like any immunological response it has to be repeated every time the outside agent evolves a counter-response. Perhaps this explains the purported benefits of 'transcending the ego' e.g. (Walsh & Vaughan [94]), which can be taken to mean getting in touch with who we were before our minds were colonized by memes, through practices such as meditation. These practices may also give the brain time to anneal material that was never fully assimilated because of distraction or censorship - mend flaws in the fabric of the individual's worldview - so that the censor-ridden personal worldview comes to more closely approximate unbiased conceptual space. Release from the restrictive power of censors may produce a feeling of unity or one-ness.

One of the things I hope the study of memetics will one day shed light on is the cumulative effect on women's self esteem of encountering the default "he" or "his", or phrases like "man and his world". Each time it happens, it reinforces, however subtly, the thought 'I'm not one of the important ones', or 'that doesn't pertain to me so I don't really count'. The effect of this may be insignificant the first few, or even hundred, times it happens. But by the time a young girl reaches adulthood, experiences of this kind probably number in the millions, and that may be when the effects start to kick in.

11 Can Cultural Evolution Provide a Synthetic Framework for the Cognitive and Social Sciences?

This paper presents a theoretical framework for cultural evolution, adopting an approach analogous to that of the population geneticist in that it emphasizes meme evolution through social interaction and de-emphasize individual 'hosts'. Although the cultural evolution of memes operates through very different mechanisms from those of biology, culture is the only system comparable to biology, because it is the only other system to exhibit the imperative features of evolution - adaptive exploration and transformation of an information space through variation, selection, and transmission. All pattern in the information we encounter can be traced to either (1) the physical constraints and self-organizing properties of matter, (2) biological evolution, (3) cultural evolution, or (4) interactions between these causal principles.

One important difference between the two forms of evolution is that culture is less random - new patterns have a greater-than-chance probability of being more fit than their predecessors. The reason for this is interesting. Since memes (unlike genomes) do not come packaged with instructions for their replication, they must rely on the pattern-evolving machinery of our brains to do it for them. Ironically, this state of dependence enhances their proliferative potential, because the machinery they depend upon constructs and continually updates mental models of its world - that is, weaves the memes into a worldview - and uses this worldview to enhance the assimilation and implementation of the memes and their offspring.

Cultural evolution presents a puzzle analogous to the origin of life: the origin of a self-sustained stream of potentially-creative thought in an infant's brain. The idea that life originated with the self-organization of a set of autocatalytic polymers suggests a possible mechanism for how this comes about. Once a threshold density of assimilated memes is surpassed, any meme that occupies the focus is close enough in Hamming distance to evoke or 'catalyze' the spontaneous retrieval or creative reconstruction of a statistically similar meme, thus the memes form an autocatalytic set. Note that this macroscopic account suggests an explanation for only that aspect of human consciousness that differentiates us from other 'experiencers'; it does not address the mystery of 'raw awareness' that some say characterizes not only our experience but that of a cow or a mosquito or even a thermostat e.g. (Chalmers [13]). Whether or not this specific theory turns out to be correct, it illustrates how the analogy to biology can focus our study of culture by providing a scaffold around which explanatory theories can be built.

The cultural framework for cognition developed here suggests tentative explanations for psychological phenomena such as censorship and creativity, and why they are virtually unique to humans. It also suggests explanations for various social phenomena. For example the telling of a

story, rumor, or joke can be viewed as an act of memetic altruism between like-minded individuals analogous to the biological altruism that occurs between genetically-similar individuals. Ongoing reciprocal interactions of this kind may result in the emergence of a memetically-derived social structure.

If we are to take seriously the idea that culture is an evolutionary process, we can look to evolution to provide the kind of overarching framework for the humanities that it provides for the biological sciences. This approach may put us on the road to understanding the pervasiveness, diversity, and adaptive complexity of the cultural debris that surrounds and infests us.

Acknowledgments

I would like to thank David Chalmers, Anthony Francis, Peter Greene, Pentti Kanerva, Ashwin Ram, Bruce Sawhill, Roger Schank, and Patrick Tufts for thoughtful comments on the manuscript.

Notes

1. Note that by 'causal principle' I mean something that generates useful descriptions, rather than a 'law'.
2. Though viruses are unique in the biological world in that they rely on hosts to replicate, we will consider viral evolution an anomalous offshoot of biological evolution, because: (1) the evolving patterns of information are encoded as sequences of nucleotides, (2) variation is through mutation and recombination, and (3) transmission and selection are mediated through genotype.
3. Or one could argue that the 'selection' of matter over antimatter, and its subsequent amplification and variation, constitutes yet another form of evolution.
4. This example is a variation of one transmitted by R. Boyd pers. com.
5. MAV has this property to some extent; a more sophisticated example is Copycat, a model of analogy-building, (Mitchell [67]).

AUTOCATALYTIC CLOSURE IN A COGNITIVE SYSTEM: A TENTATIVE SCENARIO FOR THE ORIGIN OF CULTURE

Target Article by Gabora on Origin Culture

Abstract

This target article presents a speculative model of the cognitive mechanisms underlying the transition from episodic to mimetic (or memetic) culture with the arrival of Homo Erectus, which Donald (1991) claims paved the way for the unique features of human culture. The model draws on Kauffman's (1993) theory of how an information-evolving system emerges through the formation of an autocatalytic network. Though originally formulated to explain the origin of life, Kauffman's theory also provides a plausible account of how discrete episodic memories become woven into an internal model of the world, or world-view, that both structures, and is structured by, self-triggered streams of thought. Social interaction plays a role in (and may be critical to) this process. Implications for cognitive development are explored.

Keywords: abstraction, animal cognition, autocatalysis, cognitive development, cognitive origins, consciousness, cultural evolution, memory, meme, mimetic culture, representational redescription, world-view.

I. INTRODUCTION

1. The subject of cultural origins is usually approached from an archeological perspective. For example, by dating artifacts such as tools we learn approximately when humans acquired the ability to make and use those tools. This target article takes a more cognitive approach (see also Barkow et al. 1992; Donald 1991, 1993a, 1993b; Tomasello et al. 1993; Tooby & Cosmides 1989). It outlines a theory of the psychological mechanisms underlying the major cognitive transition that, as Donald (1991) proposes, made possible the characteristic complexity and ingenuity of human culture.

2. The theory proposed here was inspired by an idea originally put forward to explain the origin of life. The origin of life and the origin of culture might appear at first glance to be very different problems. However, at a gross level of analysis they amount to the same thing: the bootstrapping of a system by which information patterns self-replicate, and the selective proliferation of some variants of these self-replicating patterns over others. The theory is thus consistent with the perspective of culture as a form of evolution (Dawkins 1975; Gabora 1997). In keeping with this

evolutionary framework, the term "meme" is used to refer to a unit of cultural information as it is represented in the brain. Thus meme refers to anything from an idea for a recipe to a memory of one's uncle to a concept of size to an attitude of racial prejudice. The rationale for lumping together episodic memories and symbolic abstractions is that they are both food for thought, units of information that can be drawn upon to invent new memes or to clarify existing ones. Memes that have been implemented as actions, vocalizations, or objects are referred to as artifacts.

3. The basic line of reasoning in this paper goes as follows. The bottleneck to cultural evolution appears to be the capacity for a self-sustained stream of thought that both structures and is structured by an internal model of the world, or world-view. It is this capacity that enables us to plan and predict, to generate novelty, and to tailor behavior according to context. The question is: Until discrete memories have been woven into a conceptual web, how can they generate a stream of thought? And conversely, until a mind can generate a stream of thought, how does it weave its memories into a world-view? Kauffman's proposal that life originated with the self-organization of a set of autocatalytic polymers suggests a mechanism for how this comes about. Much as catalysis increases the number of different polymers, which in turn increases the frequency of catalysis, reminding events increase meme density by triggering symbolic abstraction, which in turn increases the frequency of reminders. And just as catalytic polymers undergo a phase transition to a state where there is a catalytic pathway to each polymer present, and together they constitute a self-replicating set, memes undergo a phase transition to a state where each meme is retrievable through a pathway of reminders/associations, and together they constitute a transmittable world-view. In the origin of life scenario, since reactions occur in parallel, autocatalytic closure increases sharply as the ratio of reactions to polymers increases. In the cultural analog, however, the retrieval and invention of memes is funneled through an attention/awareness mechanism, which introduces a bottleneck. Therefore, this transition occurs gradually, as increasingly abstract concepts are perceived and their implications percolate through the memetic network. Social interaction and artifacts facilitate the process, and ensure that the continued evolution of memes does not hinge on the survival of any particular meme host.

II. BACKGROUND: THE ORIGIN OF LIFE AND ITS CULTURAL ANALOG

4. This section will present background material relevant to the central thesis. We begin with a comparison of minds that are and are not able to sustain cultural evolution, and we draw on what is known about human cognition to make some hypotheses concerning the differences between them. We then turn to the paradox of the origin of life, and show how autocatalysis provides a potential solution.

II.1 A TRANSITION IN COGNITIVE CAPACITY

5. In *Origins of the Modern Mind*, Donald (1991) argues convincingly that the capacity for abstract thought is the bottleneck of cultural evolution, and that it came about during the transition from episodic to mimetic culture following the arrival of *Homo Erectus* approximately 1.7 million years ago. Before this time the human memory system was like that of a primate

[FOOTNOTE 1], limited to the storage and cued retrieval of specific episodes. Donald accordingly uses the term episodic to designate a mind in which episodic memory is the only memory system there is. An episodic mind is capable of social attribution, insight and deception, and is sensitive to the significance of events. With much training it can learn arbitrary stimulus-response associations (such as pointing at a token of a certain shape to obtain food). However, it cannot invent symbols or abstractions on its own, or experiment with them. It has great difficulty accessing memories independent of environmental cues, and is unable to improve skills through self-cued rehearsal.

6. In contrast, the mimetic mind has, built upon its episodic foundations, a multimodal modeling system with a self-triggered rehearsal loop. In other words, it can retrieve and recursively operate on memories independent of environmental cues, a process referred to by Karmiloff-Smith (1992, 1994) as representational redescription. Redescribing an episode in terms of what is already known roots it in the network of understandings that comprise the world-view, and the world-view is perpetually restructured as new experiences are assimilated, and new symbols and abstract concepts are invented as needed. A mimetic individual is able to rehearse and refine skills, and therefore exhibits enhanced behavioral flexibility and more precise control over intentional communication. The upshot is cultural novelty. Mime, play, games, tool making, and reproductive memory, says Donald are thus manifestations of the same superordinate mimetic controller. The appearance of sophisticated stone tools, long-distance hunting strategies, and migration out of Africa, as well as the rapid increase in brain size at this time (Bickerton 1990; Corballis 1991; Lieberman 1991), are cited as evidence for the transition from episodic to mimetic culture. Donald claims it is not clear that the mimetic controller must be localized in any single anatomical structure, although it must have functional unity. Mimetic ability seems to encompass a broad panoply of skills associated with several distinct regions of the brain. Since miming accounts for only a small part of what the mimetic mind can do, and since mimetic skill seems to boil down to the capacity to evolve memes, we will use the term "memetic" instead of "mimetic."

7. Donald's proposal is invaluable in that spurs us to consider the cognitive basis of culture, but it leaves us hanging as to what sort of functional reorganization could turn an episodic mind into a memetic one. In particular, it leaves us with a nontrivial problem of origins. In the absence of representational redescription, how are relationships established amongst memes so that they become a world-view? And until a memory incorporates relationships between stored items, how can one meme evoke another which evokes another, etc., in a stream of representational redescription? We know that the brains of an ancestral tribe somehow turned into instruments for the variation, selection, and replication of memes. What happened to get the ball rolling, to enable the process of memetic evolution to take hold? When Grogga, a member of this tribe, had her first experience, there were no previously stored episodes to be reminded of, just external and internal stimuli (such as hunger). As episodes accumulated in her memory, occasionally it happened that an instant of experience was so similar to some stored episode that a retrieval process occurred, and she was reminded of that past episode. Perhaps the retrieval elicited a learned response. For example, the sight of a bumpy, red gourd might have reminded her of a bumpy, yellow gourd that her brother once used to carry water. Embedded in this recollection was the refreshing taste of the water he shared with her. The memory might have inspired her to use the red gourd to carry water. But since her memory consisted only of stored episodes, no

abstractions, this is the only kind of influence it could exert; her awareness was dominated by the stimuli of the present moment. At some point in her life, however, she managed to wilfully direct her attention not to a particular sensory stimulus, nor to the performance of a biological drive satisfying action, but to a chain of symbol manipulation. She kept this stream of thought going long enough to refine a concept or perspective, or invent a novel artifact. But if you need an interconnected world-view to generate a stream of thought, and streams of thought are necessary to connect individual memes into a world-view, how could one have come into existence without the other?

II.2 COGNITIVE ATTRIBUTES THAT ENABLE ABSTRACT THOUGHT

8. The first step toward an answer is to elucidate as best we can given present knowledge, the cognitive mechanisms that distinguish a memetic mind from an episodic one. This section describes a minimal, biologically plausible cognitive architecture that could qualify as memetic. This cognitive architecture is a best guess, drawn from evidence in cognitive science, neuroscience, and artificial intelligence and the knowledge that the memetic mind grew out of (and therefore the potential for it was implicit in) the architecture of the episodic mind. It has the following attributes. First, it can integrate inputs from the sensorium and the drives with inputs from memory, and it can dispense commands to the motor system. Second, the memory is sparse, content addressable, distributed, modular, and habituates to repeated inputs. This enables it to generate abstractions. Finally, it can manipulate abstractions, consciously and recursively. We discuss each attribute briefly, explain how together they accomplish a memetic task, and then specify what is most likely lacking in the episodic mind.

9. Integration of Memory, Stimuli, and Drives. Vital to both the episodic and memetic mind is a means of integrating sensations, drives, and stored memories to produce a seamless stream of conscious experience and purposeful motor action. The place where this information is coordinated need not correspond to a single anatomical structure (though it is often suggested that the intralaminar nuclei of the thalamus are involved). We will adopt Kanerva's (1988) term, the focus, since it does not imply any commitment regarding centrality or global penetration. We assume that the states of the neurons that comprise the focus determine the content and phenomenal qualities of an instant of awareness. A meme is then a high-dimensional vector of difference relations (or continuous variables) that either is or has been encoded in an individual's focus.

10. Sparse Memory. Our sensory apparatus can register a tremendous amount of information. Where n is the number of features the senses can distinguish, N , the number of memes that could potentially be hosted by the focus, $= 2^n$ for Boolean variables (n is infinitely large for continuous variables). For example, if $n = 1,000$, $N = 2^{1,000}$ memes [FOOTNOTE 2]. Assuming n is large, N is enormous, so the memory is sparse in that the number of locations L where memes can be stored is only a small fraction of the N perceivable memes. In other words, neural pathways leading out from the focus do not receive inputs from each of its n slots, but from some fraction of them. The number of different memes actually stored at a given time, s , is constrained by L . The set of all possible n -dimensional memes a mind is capable of storing can be represented as the set of vertices (if features assume only binary values) or points (if features assume continuous values) in an n -dimensional hypercube, where the s stored memes occupy

some subset of these points. The distance between two points in this space is a measure of how dissimilar they are, referred to as the Hamming distance. Kanerva (1988) makes some astute observations about this memory space. The number of memes at Hamming distance d away from any given meme is equal to the binomial coefficient of n and d , which is well approximated by a Gaussian distribution. Thus, if meme X is $111\dots 1$ and its antipode is $000\dots 0$, and we consider meme X and its antipode to be the poles of the hypersphere, then approximately 68% of the other memes lie within one standard deviation (\sqrt{n}) of the equator region between these two extremes. As we move through Hamming space away from the equator toward either Meme X or its antipode, the probability of encountering a meme falls off sharply by the proportion \sqrt{n}/n .

11. In fact the space of possibilities is even larger if we assume that the mind rarely if ever pays attention to all the stimulus dimensions it is capable of detecting. Therefore the number of dimensions the focus pays attention to, n , is only a subset of the maximum, M . The strength of the signal on a neural pathway from memory, senses, or drives must surpass some threshold before the dimension of the focus it activates is attended. Since the memory can now store memes of any length up to M , the number of possible memes is:

$$(1) N = 2^{M+1} - 2 = \text{approx: } 2^{M+1}$$

The bottom line is: the memory would probably have to be larger than the number of particles in the universe to store all the permutations of sensory stimuli it is capable of registering. It is therefore sparse.

12. Distributed Representation. In a sparse memory, the probability that a given meme in the focus is identical to one in storage is virtually zero, which means that retrieval should be impossible. In connectionist networks, this problem is solved by distributing the storage of a meme across many locations. Likewise, each location participates in the storage of many memes. The focus is represented as input/output nodes, memory locations as hidden nodes, and their pattern of connectivity as weighted links. An input touches off a pattern of activation which spreads through the network until it relaxes into a stable configuration, or achieves the desired input-output mapping using a learning algorithm. The output vector is determined through linear summation of weighted inputs. Thus a retrieved meme is not activated from a dormant state, but reconstructed. This approach is necessary if we aim to model cognition at a fine-grained level of resolution -- down to the threshold of human discrimination. There is a saying: You never step into the same stream twice; this applies to streams of thought as well as streams of water. Right now I am retrieving a memory of eating cinnamon toast; tomorrow I may retrieve the same memory. But today it is colored by today's mood, today's events; tomorrow it will be experienced slightly differently. It is not the exact same information pattern conjured up time and again. The reconstructive approach enables the memory to abstract a prototype, fill in missing features of a noisy or incomplete pattern, or create a new meme on the fly that is more appropriate to the situation than any meme it has actually experienced (Rumelhart and McClelland 1986). For example, if an autoassociative network has been fed vectors in which feature one is present whenever feature two is present, and vice versa, it will respond to an input that lacks information about feature one, such as $*101$, by generating 1101 . It may never actually have encountered 1101 before, but given that in its world there exists a correlation between features one and two, this is an appropriate response. In addition to associations between inputs and outputs of features,

the network has learned a higher-level association between two features. In effect, it contains more information than has been fed into it.

13. One problem with distributed representation is that unless stored patterns are perfectly orthogonal, they interfere with one another, a phenomenon known as crosstalk. This is solved by restricting the storage region. For instance, in Kanerva's (1988) Sparse Distributed Memory (SDM) model, a meme is stored in all locations within a hypersphere of addresses surrounding the ideal address. The smaller the Hamming distance between two memes, the more their storage locations overlap, so the higher the probability they are retrieved simultaneously and blended in the focus. A more sophisticated way of implementing this idea, for which there is neurobiological support, is to use a radial basis function (RBF) (Clothiaux et al. 1991; Hancock et al. 1991; Willshaw & Dayan 1990). Once again a hypersphere of locations is activated, but this time activation is maximal at the center of the RBF and tapers off in all directions according to a (usually) Gaussian distribution (see FIGURE 1). Where x is an i -dimensional input vector, k is the center of the RBF, and s is the width of the Gaussian, hidden nodes are activated as follows:

$$(2) F(x) = e^{-\text{SIGMA}[\left(\frac{x-k}{s}\right)^2]}$$

By carving out a hypersphere in memory space, one part of the network can be modified without affecting the capacity of other parts to store other patterns. The further a stored meme is from k , the less activation it not only receives but in turn contributes to the next evoked meme, and the more likely that its contribution is cancelled out by that of other memes. In neural networks, suitable values for k and s are found during a training phase. In the brain, k values could be modified by changing the pattern of neuronal interconnectivity. Decreasing neuron activation thresholds would increase s .

14. Organized Modularity. Another way of avoiding cross-talk is to induce a division of labor amongst competing subnetworks; in other words, to make the memory modular (Nowlan 1990; Jacobs et al. 1991). There is abundant evidence of modularity in the brain; its preservation in phylogenetic history suggests that it is not arbitrary. We assume that (1) the world we live in is highly patterned and redundant and that (2) this pattern and redundancy is reflected in the connectivity of the neurons where memes are stored. After birth there is a large-scale pruning of neurons. It seems reasonable that the surviving subset of the M possible inputs to each neural pathway is determined by biological and cultural selective pressures, instead of at random. These pressures sculpt the pattern of neuronal connectivity such that the L (out of N possible) locations can store most of the memes we stand a chance of encountering. This means that in practice the sparseness of the memory does not interfere with its representational capacity. It also means that the probability that a given stimulus activates a retrieval event is not as low as the statistics suggest.

15. Content Addressability. A computer reads from memory by simply looking at the address in the address register and retrieving the item at the location specified by that address. The sparseness of human memory prohibits this kind of one-to-one correspondence. However, content addressability can be feigned, as follows. The feature pattern that constitutes a given meme causes some neurons leading out from the focus to be excited and others to be inhibited. The ensuing chain reaction activates memory neurons where the meme gets stored. The address

of a memory neuron amounts to the pattern of excitatory and inhibitory synapses from focus to storage that make it fire, so there is a systematic relationship between the information content of a meme and the locations it activates. Thus, embedded in the neural environment that supports their informational integrity, memes act as implicit pointers to other memory locations. These pointers prompt the dynamic reconstruction of the next meme to be subjectively experienced, which is statistically similar to the one that prompted it. As a result, the entire memory does not have to be searched in order for a gourd to remind Grogga of a previously encountered gourd. It is worth stressing that there is no search taking place, just information flowing through a system displaced from equilibrium. The current instant of experience activates certain neurons, which in turn activate certain other neurons, which leads to the distributed storage of that experience, which activates whatever else is stored in those locations, which then merges with any salient information from the senses and drives to form the next instant of experience, etc. in an ongoing cycle. What emerges is that the system appears to retrieve memories that are similar, or concepts that are relevant, to the current experience. But that is not magic; it is simply a side effect of the fact that correlated memes get stored in overlapping locations.

16. Habituation. We do not want an ongoing stimulus, such as the sound of rain, to recursively evoke reminders of rain. The nervous system avoids this kind of perseveration as follows. First, neurons have a refractory period during which they cannot fire, or their response is greatly attenuated. Second, they team play; the responsibility for producing a response is shared by a cooperative group of neurons such that when one is refractory another is active. If exactly the same neurons are stimulated repeatedly, they all become refractory, and there is little or no response.

17. Capacity for Symbol Manipulation. The connectionist methods described above are examples of the subsymbolic approach to cognition, which works best for modelling perceptual and low-level cognitive phenomena. These include detecting, representing, and responding flexibly to patterns of correlation, learning fuzzy categories, and solving simple constraint satisfaction problems. Subsymbolic processing makes the world easier to navigate. But the world contains additional structure that our brains are not hard-wired to capture. Therefore, even after memes are stored in memory, they are clustered, rather than being uniformly distributed throughout the space of possible memes; and they contain implicit predicate logic relationships. This is where symbolic processing is useful. Symbolic models of cognition focus on the serial and potentially recursive application of logical operations on symbols, without attempting to represent their internal structure. They are particularly good at modeling the high-level cognitive abilities that are unique to memetic minds, such as planning and deductive reasoning. Arguments for a reconstructive view of retrieval notwithstanding, highly abstract concepts that have been used thousands of times, such as "space" or "equal" or "is," would be unlikely to emerge from memory retaining the associations of any particular usage. Thus it seems reasonable to begin with the working hypothesis that subsymbolic processing predominates for low-level, parallel, automatically generated cognitive phenomena, and that symbolic processing provides a satisfactory approximation for many high-level, serial, consciously directed aspects of cognition. (Creative processes may draw heavily on both.)

18. Let us now examine how a cognitive architecture with these attributes would accomplish a specific task. Consider the situation wherein the sight of a rotting, striped, bumpy, red gourd

reminds Groga of the striped, bumpy, yellow gourd her brother used as to carry water, which generates the desire to have water readily available in the cave. Groga slashes the top off the red gourd and scoops water into it. To her dismay, the water leaks out through a soft decay spot. Just out of sight lies the intestine of a recently killed water buffalo. What sort of cognitive dynamics would prompt Groga to tie one end of the intestine and use it as a waterbag? It is unlikely that the ability to classify gourd and knotted intestine as potentially substitutable instances of the category container is hard-wired. No one in Groga's tribe has previously conceived of an intestine as a container, so social learning is not an option. This task involves a number of difficult skills including abstract reasoning, uncued retrieval, redescription, and manual dexterity. It lies beyond the horizon of what the episodic mind can accomplish.

19. The sight of the red gourd is registered as a vector of features in Groga's focus. This vector determines which synapses leading out from the focus are excited and which are inhibited, which determines how activation flows through her memory network, which in turn determines the hypersphere of locations where "red gourd" is stored. The process of storing to these neurons triggers retrieval from these neurons of whatever has been stored in them. Of course, nothing is retrieved from them if, after red gourd is stored, Groga's attention is directed toward some stimulus or biological drive. But to the extent that memory contributes to the next instant of awareness, storage of red-gourd activates the retrieval of not only red-gourd itself but all other memes stored in the same locations. The next meme to be encoded in the focus is found by evaluating the contributions of all retrieved memes feature-by-feature. Whereas the retrieved copies of red gourd reinforce one another, the other retrieved memes contribute less, and are statistically likely to cancel one another out. They do not cancel out exactly, however, unless the distribution of stored memes within the hypersphere of activated locations is uniformly dense. In this case it is not. The meme yellow gourd container, which got stored when Groga saw her brother carrying water in a yellow gourd, acts as an attractor. The result is that the next meme ends up being red gourd container. Though it is a reconstructed blend, something Groga has never actually experienced, it can still be said to have been retrieved from memory.

20. Groga pours water into the red gourd and, as we know, it leaks out. Her mental model of the world was in error; not all gourds can transport water. Stymied, memory is probed again, with knowledge of relationships between objects and attributes guiding the process. The second probing occurs with intensified activation of the pathway leading from the concave slot of the focus, and inhibition of the permeable slot. Let us now focus on the portion of Groga's memory that deals with four discrete features: bumpy, striped, permeable, and concave (FIGURE 2). These lie on the x_1 , x_2 , x_3 , and x_4 axes, respectively, and a black dot represents the center of a distributed hypersphere where a meme is stored. The second probing of memory activates a slightly different set of locations, which evoke the abstract category container, the class of objects that are concave and impermeable, and for which the attributes bumpy and striped are irrelevant. Container was implicit in the meme-space; it covered the two-dimensional yellow region of the original hypercube. More generally, we can view an n -dimensional meme space as a set of nested hypercubes, such that implicit in the outermost hypercube of memes with all n dimensions there exist hypercubes of memes with $n-1$ dimensions, $n-2$ dimensions, etc. Armed with the category container, Groga dips into memory again to discover what else constitutes a member of this category. The closest thing she can come up with is intestine. Symbol manipulation now kicks in. She realizes that the intestine is impermeable and almost concave.

Knotted at one end, an intestine would constitute another member of the category container. She could therefore carry water in it. She runs off to fetch the intestine.

21. The foregoing discussion may be wrong in the details, but hopefully it captures the gist of memetic cognition. Now we ask: what is the episodic mind lacking? Some are tempted to say that the ability of animals to respond appropriately to salient stimuli, and even learn arbitrary sensorimotor associations, indicates some capacity for symbolic thought. However, animals' learned behavior is stereotyped and brittle: it cannot be adapted to new contexts, which suggests that they use symbols only in an iconic sense. They give no indication of engaging in streams of thought that reorganize memes in ways that make their similarities and differences more explicit. They could not retrieve the memory that an intestine is in the cave, much less realize that it was relevant to the goal of transporting water. Our best-guess model of cognition suggests a number of possible reasons. First, the resolution of the perceptual apparatus might not be high enough to capture enough features of salient stimuli (large M). Second, there might not be enough memory locations to keep these distinctions intact during storage (large L). Third, the density s/N of stored memes might be too low. In other words, there might not be enough different basins of attraction for memes to slide into, or not enough of these attractors might be occupied. Another possibility is that the neuron activation threshold is too high (and thus s too narrow). The end result is the same in all cases: rarely is there a stored meme within retrievable distance of a given meme in the focus. Thus the memory does not encode relationships, so rarely can a stream of interrelated thoughts ensue. In fact, these explanations are connected. M limits L , which in turn limits s . And since if $s \rightarrow 0$, the memory only retrieves memes identical to the content of the focus and therefore cannot form abstractions, s also limits s .

22. At this point we are in a position to reframe our central question. We want to know how a mind comes to assume a self-sustained stream of thought that progressively shapes and is shaped by, a world-view. Abstract thinking requires each meme that enters the focus to activate one or more memes already stored in memory enough to evoke a retrieval. The memory must be traversed with tunnels that connect related concepts like an apple crisscrossed with wormholes. However, representational redescription is the process that puts related memes within working memory reach of one another; it is what recognizes abstract similarities and restructures the memory to take them into account. How do you get the wormholes without the worms?

II.3 THE ORIGIN OF LIFE PARADOX

23. We will put aside the question of cultural origins for now, and turn to the problem of biological origins. The paradox of the origin of life can be stated simply: if living things come into existence when other living things give birth to them, how did the first living thing arise? That is, how did something complex enough to reproduce itself come to be? In biology, self-replication is orchestrated through an intricate network of interactions between DNA, RNA, and proteins. DNA is the genetic code; it contains instructions for how to construct various proteins. Proteins, in turn, both catalyze reactions that orchestrate the decoding of DNA by RNA, and are used to construct a body to house and protect all this self-replication machinery. Once again, we have a chicken-and-egg problem. If proteins are made by decoding DNA, and DNA requires the catalytic action of proteins to be decoded, which came first? How could a system composed of complex, mutually dependent parts come into existence?

24. The most straightforward explanation is that life originated in a prebiotic soup where, with enough time, the right molecules collided into one another at the same time and reacted in exactly the right ways to create the DNA-RNA-protein amalgam that is the crux of life as we know it. Proponents argue that the improbability of this happening does not invalidate the theory because it only had to happen once; as soon as there was one self-replicating molecule, the rest could be copied from this template. Miller (1955) increased the plausibility of this hypothesis by showing that amino acids, from which proteins are made, form spontaneously when a reducing [FOOTNOTE 3] mixture of oxygen, hydrogen, carbon, nitrogen, water, and ammonia is subjected to high energy. These molecules were all likely to have been present on the primitive earth, and energy could have come in the form of electric discharges from thunderstorms, ultraviolet light, or high temperatures generated by volcanoes. Other experiments have shown that the molecular constituents of DNA and RNA, as well as the fatty acids from which membranes are constructed, can be formed the same way. Unfortunately, the complexity of the DNA-RNA-protein structure is so great, and in the earth's early atmosphere the concentrations of the necessary molecules were so dilute, that the probability of life originating this way is infinitesimally low. Hoyle and Wickramasinghe (1981) likened it to the probability that a tornado sweeping through a junkyard would spontaneously assemble a Boeing 747.

25. The less complex something is, the more feasible its spontaneous generation. The discovery of ribozymes -- RNA molecules that, like proteins, are capable of catalyzing chemical reactions - brought the hope that the first living molecule had been found. With ribozymes you would not need DNA or proteins to establish a self-replicating lineage; these RNA molecules would do the job of all three. In practice, however, self-replication of RNA is fraught with difficulties. It tends to fold back on itself creating an inert, tangled mess (Joyce, 1987). Furthermore, the probability of a ribozyme assembling spontaneously from its components is remote (Orgel 1987), and even if it managed to come into existence, in the absence of certain error-detecting proteins found in all modern-day organisms, its self-replication capacity would inevitably break down in the face of accumulated error over successive generations (Eigen and Schuster, 1979). Thus it is far from obvious how the chain of self-replicating systems that eventually evolved into you and me got started.

II.4 THE AUTOCATALYSIS THEORY OF THE ORIGIN OF LIFE

26. Despite the myriad difficulties encountered attempting to get ribozymes to self-replicate, the idea behind it -- that life originated in a simple self-replicating system that over time evolved into the familiar DNA-RNA-protein complex -- was a good one. Once you have some sort of self-replicating structure in place, anything whatsoever that accomplishes this basic feat, natural selection can enter the picture and help things along. Kauffman (1991) suggested that knowing as much as we do about what life is like now may actually get in the way of determining how it began. He accordingly decided to focus on how to get from no life at all to any kind of primitive self-replicating system, and to hand the problem of getting from there to DNA-based life, over to natural selection (as well as self-organizing processes). Given the conditions present on earth at the time life began, how might some sort of self-replicating system have arisen? His answer is that life may have begun not with a single molecule capable of replicating itself, but with a set of collectively self-replicating molecules. That is, none of the molecules could replicate itself, but each molecule could induce the replication of some other molecule in the set, and likewise, its

own replication was induced by some other member of the set. This kind of dual role as both ingredient (or stimulant) and product of different chemical reactions is not uncommon for polymers such as protein and RNA molecules.

27. Polymers induce each other's replication by acting as catalysts. Catalysts speed up chemical reactions that would otherwise occur very slowly. An autocatalytic system is a set of molecules which, as a group, catalyze their own replication. Thus, if A catalyzes the conversion of X to B, and B catalyzes the conversion of Y to A, then A + B comprise an autocatalytic set (FIGURE 3). In an environment rich in X and Y, A + B can self-replicate. A set of polymers wherein each molecule's formation is catalyzed by some other molecule is said to exhibit catalytic closure.

28. It is of course highly unlikely that two polymers A and B that just happened to bump into one another would happen to catalyze each other. However, this is more likely than the existence of a single polymer catalyzing its own replication. And in fact, when polymers interact, their diversity increases, and so does the probability that some subset of the total reaches a critical point where there is a catalytic pathway to every member. To show that this is true we must show that the number of reactions by which they can interconvert increases faster than their total number. Given polymers made up of, say, two different kinds of monomers, of up to a maximum length of M monomers each, then N, the number of polymers, is 2^{M+1} as per equation (1). Thus as M increases -- which it obviously does, since two of the longest polymers can always join to form a longer one -- the number of polymers increases exponentially. Now we need to show that the number of reactions between them increases even faster. We will be conservative and consider only cleavage (e.g. 110 -> 1 + 10) and ligation (e.g. 1 + 10 -> 110) reactions on oriented polymers (such as protein and RNA fragments). The number of possible reactions R is the product of the number of polymers of a certain length times the number of bonds, summed across all possible lengths:

$$(3) R = (2^M)(M-1) + (2^{M+1})(M-2) + \dots + (2^{M-(M-2)})(M-(M-1))$$

<ftp://coglit.psy.soton.ac.uk/pub/psycoloquy/1998.volume.9/Pictures/eqn3a.jpg>

$$= \sum_{n=2}^M (2^n)(n-1)$$

Dividing equation (3) by equation (1), we find that as M increases, the ratio of reactions to polymers increases by a factor of M-2. This means that if each reaction has some probability of getting carried out, the system eventually undergoes a transition to a state where there is a catalytic pathway to each polymer present. The probability of this happening shifts abruptly from highly unlikely to highly likely as R/N increases. This kind of sharp phase transition is a statistical property of random graphs and related systems such as this one. Random graphs consist of dots, or nodes, connected to each other by lines or edges. As the ratio of edges to nodes increases, the probability that any one node is part of a chain of connected nodes increases, and chains of connected nodes become longer. When this ratio reaches approximately 0.5, almost all these short segments become cross-connected to form one giant cluster (FIGURE 4). Plotting the size of the largest cluster versus the ratio of edges to nodes yields a sigmoidal curve. The larger the number of nodes, the steeper the vertical portion of this curve (referred to as the percolation threshold).

29. Of course, even if catalytic closure is theoretically possible, we are still a long way from knowing that it is the correct explanation for the origin of life. How likely is it that an autocatalytic set would have emerged given the particular concentrations of chemicals and atmospheric conditions present at the time life began? In particular, some subset of the R theoretically possible reactions may be physically impossible; how can we be sure that every step in the synthesis of each member of an autocatalytic set actually gets catalyzed? Kauffman's response is: if we can show that autocatalytic sets emerge for a wide range of hypothetical chemistries (i.e., different collections of catalytic molecules), then the particular details of the chemistry that produced life do not matter so long as it falls within this range. We begin by noting that, much as several different keys sometimes open the same door, each reaction can be catalyzed by not a single catalyst, but a hypersphere of catalytic molecules, with varying degrees of efficiency. So we assign each polymer an extremely low a priori random probability P of catalyzing each reaction. The lower the value of P, the greater M must be, and vice versa. Kauffman shows that the values for M and P necessary to achieve catalytic closure with a probability of < 0.999 are highly plausible given the conditions of early earth. Experimental evidence for this theory using real chemistries (Lee et al. 1996, 1997; Severin et al. 1997), and computer simulations (Farmer, et al. 1986) have been unequivocally supportive. Farmer et al. showed that in an artificial soup of information strings capable of cleavage and ligation reactions, autocatalytic sets do indeed arise for a wide range of values of M and P.

30. An interesting question explored in this simulation is: once a set of polymers has achieved autocatalytic closure, does that set remain fixed, or is it able to incorporate new polymer species? Farmer et al. found that some sets were "subcritical" (unable to incorporate new polymers) and others were "supracritical" (incorporated new polymers with each round of replication). Which of these two regimes a particular set fell into depended on P, and the maximum length of the food set polymers.

31. Now the question is: supposing an autocatalytic set did emerge, how would it evolve? The answer is fairly straightforward. It is commonly believed that the primitive self-replicating system was enclosed in a small volume such as a coascervate or liposome to permit the necessary concentration of reactions (Oparin 1971; Morowitz 1992; Cemin & Smolin, in press). Since each molecule is getting duplicated somewhere in the set, eventually multiple copies of all molecules exist. The abundance of new molecules exerts pressure on the vesicle walls. This often causes such vesicles to engage in a process called budding, where it pinches off and divides into two twins. So long as each twin contains at least one copy of each kind of molecule, the set can continue to self-replicate indefinitely. Replication is far from perfect, so an offspring is unlikely to be identical to its parent. Different chance encounters of molecules, or differences in their relative concentrations, or the arrival of new food molecules, could all result in different catalysts catalyzing a given reaction, which in turn alters the set of reactions to be catalyzed. So there is plenty of room for heritable variation. Error catastrophe is unlikely because, as mentioned earlier, initially each reaction can be catalyzed not by a single catalyst but by a hypersphere of potential catalysts, so an error in one reaction does not have much effect on the set at large [FOOTNOTE 4]. Selective pressure is provided by the affordances and limitations of the environment. For example, say an autocatalytic set of RNA-like polymers arose. Some of its offspring might have a tendency to attach small molecules such as amino acids (the building blocks from which proteins are made) to their surfaces. Some of these attachments inhibit

replication, and are selected against, while others favor it, and are selected for. We now have the beginnings of the kind of genotype-phenotype distinction seen in present-day life. That is, we have our first indication of a division of labor between the part of the organism concerned with replication (in this case the RNA) and the part that interacts with the environment (the proteins)

32. The autocatalytic origin of life theory circumvents the chicken-and-egg problem by positing that the same collective entity is both code and decoder. This entity does not look like a code in the traditional sense because it is a code not by design but by default. The code is embodied in the physical structures of the molecules; their shapes and charges endow them with propensities to react with or mutually decode one another such that they manifest external structure, in this case a copy of its collective self. Since autocatalytic sets appear to be a predictable, emergent outcome in any sufficiently complex set of polymers, the theory suggests that life is an expected outcome rather than a lucky long-shot.

III. THE EMERGENCE OF AUTOCATALYSIS IN A COGNITIVE SYSTEM

33. We have taken a look at two paradoxes -- the origin of culture and the origin of life -- which from hereon will be referred to as OOC and OOL respectively. The parallels between them are intriguing. In each case we have a self-replicating system composed of complex, mutually interdependent parts, and since it is not obvious how either part could have arisen without the other, it is an enigma how the system came to exist. In both cases, one of the two components is a storehouse of encoded information about a self in the context of an environment. In the OOL, DNA encodes instructions for the construction of a body that is likely to survive in an environment like the one in which its ancestors survived. In the OOC, an internal model of world encodes information about the self, the environment, and the relationships between them. In both cases, decoding a segment of this information storehouse generates another class of information unit that coordinates how the storehouse itself gets decoded. Decoding DNA generates proteins that, in turn, orchestrate the decoding of DNA. Retrieving a memory or concept from the world-view and bringing it into awareness generates an instant of experience, a meme, which in turn determines which are the relevant portion(s) of the world-view to use in constructing the next instant of experience. In both cases it is useful to think of the relevant class of information units as states in an information space, each of which can act on a hypersphere of other states. In the memory model it was the hypersphere of related memes, and in the OOL model it was the hypersphere of potential catalysts.

34. We have argued that the most likely bottleneck in the OOC is the establishment of a network of inter-related memes, a world-view, that progressively shapes and is shaped by a stream of self-triggered thought. We want to determine how such a complex entity might come to be. Donald claims that the transition from episodic to memetic culture would have required a fundamental change in the way the brain operates. Drawing from the OOL scenario presented above, we will explore the hypothesis that meme evolution begins with the emergence of a collective autocatalytic entity that acts as both code and decoder. This idea was mentioned briefly in Gabora (1996a; 1996b; 1997); here it is fleshed out in greater detail.

III.1 ESTABLISHING THE CAPACITY FOR ABSTRACTION

35. In the OOL case we asked: what was lying around on the primitive earth with the potential to form some sort of self-replicating system? The most promising candidate was catalytic polymers, the molecular constituents of either protein or RNA. Here we ask an analogous question: what sort of information unit does the episodic mind have at its disposal? It has memes, specifically memories of episodes. Episodic memes then constitute the food set of our system.

36. Next we ask: what happens to the food set to turn it into a self-replicating system? In the OOL case, food-set molecules catalyzed reactions on each other that increased their joint complexity, eventually transforming some subset of themselves into a collective web for which there existed a catalytic pathway to the formation of each member molecule. An analogous process might conceivably transform an episodic mind into a memetic one. Food-set memes activate redcriptions of each other that increase their joint complexity, eventually transforming some subset of themselves into a collective web for which there exists a retrieval pathway to the formation of each member meme. Much as polymer A brings polymer B into existence by catalyzing its formation, meme A brings meme B into conscious awareness by evoking it from memory. As in Section II.2, a retrieval can be a reminding, a redescription of something in light of new contextual information, or a creative blend or reconstruction of many stored memes.

37. How might Grogga's mind have differed from that of her ancestors such that she was able to initiate this kind of transformation? In the OOL case, it was crucial that the polymers be catalytic. We simply gave each polymer a small, random probability P of catalyzing each reaction. In the OOC case, we assume that each of Grogga's L memory locations where the memes are stored has a RBF with a Gaussian distribution of width s centered on it. Thus the probability that one meme evokes another is determined by s rather than a random probability P . Let us consider what would happen if, due to some genetic mutation, Grogga's activation threshold were significantly lower than average for her tribe. Thus s is wider, which means that a greater diversity of memes are activated in response to a given experience, and a larger portion of the contents of memory merge and surface to awareness in the next instant. Since the memory is content-addressable, when meme X goes fishing in memory for meme X , sooner or later this large hypersphere is bound to catch a stored meme that is quite unlike X . For example, let us say that Grogga sees rabbits every day, so there are lots of rabbit memories stored in her brain. For simplicity, let us say they consist of a sequence of ten 0's followed by a five bit long variable sequence. She happens to look off in the distance and see a grazing water buffalo, which gets represented in her focus as 000000011101010. The buffalo meme will be referred to as meme X . Because the hypersphere is wide, all the rabbit memories lie close enough to meme X to get evoked in the construction of X (as is X itself). Since all the components from which X is made begin with a string of seven zeros, there is no question that X also begins with a string of seven zeros. These positions might code for features such as has eyes, eats, etc. The following set of three 1's in the rabbit memes are cancelled out by the 0s in the buffalo memes, so in X they are represented as *s These positions might code for features such as floppy ears. The last five bits constituting the variable region are also statistically likely to cancel one another out. These code for other aspects of the experience, such as, say, the color of the sky that day. So X turns out to be the meme 0000000*****, the generic category animal;, which then gets stored in memory in the next iteration. This evocation of animal by the buffalo episode is not much of a stream of thought, and it does not bring her much closer to an interconnected conceptual web, but it is an

important milestone. It is the first time she ever derived a new meme from other memes, her first creative act.

III.2 ESTABLISHING A STREAM OF THOUGHT

38. Although lowering the neuron activation threshold was what enabled Grogga to create an abstraction, the penalty for having too low a threshold would be very high, because successive thoughts would not necessarily be meaningfully related to one another. Abstract thought, unlike episodic thought, cannot rely on the continuity of the external world (i.e., if a desk is in front of you now it is likely to still be in front of you now) to lend coherence to conscious experience. Too low a threshold might be expected to result in a cognitive rendition of superconductivity, where lowering resistance increases correlation distance and thus a perturbation to any one pattern percolates through the system and affects even distantly related patterns. (The free-association of a schizophrenic seems to correspond to what one might expect of a cognitive system with this property (see Weisberg 1986).) However, if the threshold is extremely high, such that distributions do not overlap, the attended meme must be identical to one stored in memory to evoke a retrieval. To produce a steady stream of meaningfully related yet potentially creative reminders, the threshold must fall within an intermediate range. This is consistent with Langton's (1992) finding that the information-carrying capacity of a system is maximized when its interconnectedness falls within a narrow regime between order and chaos.

39. Thus thoughts do not leap from one unexplored territory of meme-space to another, but meander from one meme to a similar one in a region that has proven fruitful and is therefore exceptionally clustered with memes. This not only increases the frequency of reminders and abstractions, it provides a thread of continuity linking one meme to the next. Organized modularity also enhances continuity by precluding the activation of irrelevant memes. Since statistical similarity is preserved across sequentially evoked memes in a train of thought, thinking can be viewed as an internal form of meme self-replication. It could be argued that the correlation between consecutive memes is so low that this hardly deserves to be called a form of self-replication. One would not want consecutive memes to be identical. Surely Eigen and Schuster's error catastrophe argument applies here; that is, the copying fidelity of this process is so low that errors would quickly accumulate and in no time the lineage would die. But this argument does not apply. The only reason it is a pitfall for biological evolution is that copying error tends to impair the capacity to self-replicate. So long as offspring are as good as their parents at reproducing themselves, and live long enough to do so, it does not matter how much error is introduced from one generation to the next. It is only when a generation dies without having reproduced that there is a problem. In the biological world, once something is dead it cannot bring forth life [FOOTNOTE 5]. But in memetic evolution this is not necessarily the case. To show why this is so, say that half-way through the train of consecutive memes in Einstein's brain that culminated in the theory of relativity, a tiger burst in through the window. The correlation between the relativity meme of one instant and the tiger-perception-meme of the next instant would be almost zero. This momentous memetic lineage would come to a screeching halt. But would it be lost forever? No. Sooner or later, once the tiger situation was taken care of, the relativity stream of thought would resume itself. Memory (and external artifacts) function as a memetic sperm bank, allowing a defunct ancestral line to be brought back to life and to resume

self-replication. The upshot is that in culture you can get away with a much higher error rate than in biology.

40. Cultural evolution has not only an internal form of replication, but also an internal means of generating variation. In a stream of thought, consecutive memes are not exact replicas; each meme is a variation of its predecessor. It also has an internal form of selection. Selection comes in the form of drives, needs, attention-focusing mechanisms, and the associative organization of memory, which constrain how one meme evokes another. Thus all the components of an evolutionary process take place in the mind of an isolated individual. The memory-driven generation of a stream of correlated memes can be viewed as a coevolutionary relationship between replication, variation, and selection, and the process of representational redescription can itself be redescribed as the selective generation of variant replicants. Embedded in the outer, inter-individual sheath of memetic evolution we find a second intra-individual sheath, where the processes of replication, variation, and selection are not spatiotemporally separated but intimately intertwined. Together they weave a stream of thought, one meme fluidly transmuting into the next.

41. Thus the semantic continuity of a stream of thought makes memory navigable despite its sparseness. Once "animal" has been evoked and stored in memory, the locations involved habituate and become refractory (so, for instance, animal does not recursively evoke animal). However locations storing memes that have some animal features, but that were not involved in the storage of animal, are still active. Thus animal might activate "tiger" which might evoke "hyena" etc., strengthening associations between the abstract category and its instances. Other abstractions, such as container, form in analogous fashion. As Grogga accumulates both episodic memes and abstractions, the probability that any given attended meme is similar enough to some previously stored meme to activate it increases. Therefore reminding acts increase in frequency, and eventually become streams of reminders, which get progressively longer. Grogga is now capable of a train of thought. Her focus is no longer just a spot for coordinating stimuli with action; it is now a forum for abstractive operations that emerge through the dynamics of iterative retrieval.

III.3 AUTOCATALYTIC CLOSURE IN A WEB OF SPARSE, DISTRIBUTED MEMES

42. We have seen how our best-guess model of human cognition achieves a stream of thought. How do we know that streams of thought will induce a phase transition to a critical state where for some subset of memes there exists a retrieval pathway to each meme in the subset? In the OOL case, we had to show that R , the number of reactions, increases faster than N , the number of polymers. We found that R/N increased by a factor of M^2 , where M was the maximum number of monomers per polymer. Because of the highly parallel nature of this system, it was reasonable to equate potential reactions with actual reactions, and therefore to assume that the new polymers resulting from these reactions actually exist (and can themselves partake in reactions). Similarly, we now want to show that some subset of the memes stored in an individual's mind inevitably reach a critical point where there is a path by which each meme in that subset can get evoked. But here, it is not reasonable to assume that all N perceptible memes actually exist (and can therefore partake in retrieval operations). Their number is severely curtailed by the number of memory locations, the variety of perceptual experience, and the fact

that meme retrieval, though distributed at the storage end, is serial at the awareness end. The rate at which streams of thought reorganize the memetic network is limited by the fact that everything is funneled through the focus; we can only figure one thing out at a time. This presents a bottleneck that was not present in the OOL scenario. As a result, whereas OOL polymers underwent a sharp transition to a state of autocatalytic closure, any analogous transition in inter-meme relatedness is expected to take place gradually. So we need to show that R , the diversity of ways one meme can evoke another, increases faster than N but s , the number of memes that have made it through this bottleneck. That is, as the memory assimilates memes, it comes to have more ways of generating memes than the number of memes that have explicitly been stored in it.

43. This brings us to another complication, which further prolongs cognitive development. Since short, simple molecules are more abundant and readily formed than long, complex ones, in the OOL case it made sense to expect that the food set molecules were the shortest and simplest members of the autocatalytic set that eventually formed. Accordingly, in simulations of this process the direction of novelty generation is outward, joining less complex molecules to form more complex ones through AND operations. In contrast, the memetic food set molecules are complex, consisting of all attended features of an episode. In order for them to form an interconnected web, their interactions tend to move in the opposite direction, starting with relatively complex memes and forming simpler, more abstract ones through OR operations. The net effect of the two is the same: a network emerges, and joint complexity increases. But what this means for the OOC is that there are numerous levels of autocatalytic closure, which convey varying degrees of world-view interconnectedness and consistency on their meme host. These levels correspond to increased penetration of the $(n-1, n-2)$ -dimensional nested hypercubes implicit in the memory space. Since it is difficult to visualize a set of nested, multidimensional hypercubes, we will represent this structure as a set of concentric circles, such that the outer skin of this onion-like structure represents the hypercube with all n dimensions, and deeper circles represent lower-dimensional hypercubes. Obviously, not all the nested hypercubes can be shown. The points of our original hypercube are represented as points along the perimeter of these circles, and k values (centermost location where a meme is stored) are shown as large, black dots. The outermost shell encodes memes in whatever form they are in the first time they are consciously encountered. This is all the episodic mind has to work with. In order for one meme in this shell to evoke another, they have to be extremely similar at a superficial level. In a memetic mind, however, related concepts are within reach of one another because they are stored in overlapping hyperspheres.

44. Under what conditions does that R increase faster than s ? As it turns out, abstraction plays a crucial role. To determine how abstraction affects R , let us assume for the moment that memory is fully connected. Clearly this is not the case, but this simplification illustrates some trends which also apply to a memory wherein sparseness is compensated for by restricted distributed activation. We will be conservative and limit the sort of retrieval event under consideration to abstraction, and the redescription of a meme as an instance of an abstraction (including analogical thought). Abstractions have n dimensions, where n ranges from a minimum of m to a maximum of M . R_{subA} , the number of ways a retrieval can occur through abstraction, equals the number of retrieval paths allowed by an n -dimensional abstraction, multiplied by the number of n -dimensional abstractions, summed over all values of n from m to $M-1$. The number of

retrieval paths equals the number of memes that are instances of an n-dimensional abstraction = $2^{(M-n)}$. The number of n-dimensional abstractions is equal to the binomial coefficient of M and n. The result is multiplied by two, since an abstraction can evoke an instance, and likewise, an instance can evoke an abstraction.

$$(4) R_{subA} = 2(2^{(M-m)}[M::m] + 2^{(M-(m+1))}[M::m+1] + \dots + 2[M::M-1]) \\ = 2(\text{SIGMA}(2^{(M-n)}[M::n]) \text{ for } (n-m) \rightarrow M-1)$$

The key thing to note is that lower-dimensional memes allow exponentially more retrieval paths. Abstraction increases s by creating a new meme, but it increases R more, because the more abstract the concept, the greater the number of memes a short Hamming distance away (since $|x_i - k_i| = 0$ for the irrelevant dimensions). A second thing to note is that the number of abstractions at a given value of n increases up to $M/2$. Taken together, these points mean: the more deeply a mind delves into lower-dimensional abstractions, the more the distribution rises and becomes skewed to the left. The effect is magnified by the fact that the more active a region of meme space, the more likely that an abstraction will be positioned there, and thus abstractions beget abstractions recursively through positive feedback loops. Reminding incidents also contribute to R . Hence the more likely it is that some meme will get activated and participate in a given retrieval. So, whereas R increases as abstraction makes relationships increasingly explicit, s levels off as new experiences have to be increasingly unusual in order to count as new and get stored in a new constellation of locations. Furthermore, when the carrying capacity of the memory is reached, s plateaus, but R does not. Thus as long as the neuron activation threshold is large enough to permit abstraction and small enough to permit temporal continuity, the average value of n decreases. Sooner or later the system is expected to reach a critical percolation threshold such that R increases exponentially faster than s .

45. So long as R does indeed eventually increase faster than s , Grogga's memory becomes so densely packed that any meme that comes to occupy the focus is bound to be close enough in Hamming distance to some previously stored meme(s) to evoke it. The memory (or some portion of it) is holographic in the sense that there is a pathway of associations from any one meme to any other. Together they form an autocatalytic set. What was once just a collection of isolated memories is now a structured network of concepts, instances, and relationships -- a world-view. This most primitive level of autocatalytic closure is achieved when stored episodes are interconnected by way of abstractions just a few onion-skin layers deep, and streams of thought zigzag amongst these superficial layers. A second level occurs when relationships amongst these abstractions are identified by higher-order abstractions at even deeper onion-skin layers, etc. Once Grogga's memory has defined an abstraction, identified its instances, and chunked them together in memory, she can manipulate the abstraction much as she would a concrete episode. Reflecting on an idea amounts to reflecting it back and forth off onion-skin layers of varying depths, refining it in the context of its various interpretations. The conscious realization of the logical operators and, or and not, are expected to significantly transform Grogga's world-view by enabling conscious symbol manipulation. Other particularly useful abstractions such as mine, depth, or time, as well as frames (Barsalou, in press), scripts (Schank & Abelson 1977), and schemas (Minsky 1985), are also expected to induce reorganization. Just as in a sand pile perched at the proverbial edge of chaos a collision between two grains occasionally triggers a chain reaction that generates a large avalanche, one thought occasionally triggers a chain reaction of others that

dramatically reconfigure the conceptual network. Rosch's (1978) work on basic level categories suggests that the way we organize information is not arbitrary but emerges in such a way as to maximize explanatory power. It would not be surprising to find that the number of categories and their degree of abstraction exhibit the same kind of power law relationship as one finds in other emergent systems (Bak, Tang, & Weisenfeld 1988).

46. How does an interconnected world-view help Grogga manifest the skills that differentiate a memetic mind from an episodic one? The capacity to maintain a stream of self-triggered memes enables her to plan a course of action, and to refine behavior by incorporating kinesthetic feedback into a meme sequence. The ability to generate abstractions opens up a vast number of new possibilities for Grogga. It allows her to incorporate more of the structure of the world into her mental model of it. This increases behavioral flexibility by enabling her to define elements of the world in terms of their substitutable and complementary relationships. (For example, if she usually makes bows out of wood X, but she cannot find any wood X, and if wood Y is as strong and flexible as wood X, then wood Y might substitute for wood X.) The power of abstraction also enables her to express herself artistically by extricating memes from the constraints of their original domain and filtering the resulting pattern through the constraints of other domains. For example, she can translate the scene before her into a sequence of motor commands that render it as a cave painting or stone carving, or transform the pattern of information that encodes the sorrow she experienced at her child's death into a song. Finally, abstraction enables Grogga to communicate with others through spoken or nonverbal forms of language. This brings us to the issue: how does the world-view replicate?

III.4 SOCIAL INTERACTION FACILITATES WORLD-VIEW EMERGENCE

47. Now that we have an autocatalytic network of memes, how does it self-replicate? In the OOL scenario, polymer molecules accumulate one by one until there are at least two copies of each, and their shell divides through budding to create a second replicant. In the OOC scenario, Grogga shares concepts, ideas, stories, and experiences with her children and tribe members, spreading her world-view meme by meme. Categories she had to invent on her own are presented to and experienced by others much as any other episode. They are handed a shortcut to the category; they do not have to engage in abstraction to obtain it.

48. Recall how the probability of autocatalysis in Kauffman's simulation could be increased by raising either the probability of catalysis or the number of polymers (since it varied exponentially with M). Something similar happens here. Eventually, once enough of Grogga's abstractions have been assimilated, her tribe members' memories become so densely packed that even if their neuron activation thresholds are higher than Grogga's, a version of Grogga's world-view snaps into place in their minds. Each version resides in a different body and encounters different experiences. These different selective pressures sculpt each copy of Grogga's original world-view into a unique internal model of the world. Small differences are amplified through positive feedback, transforming the space of viable world-view niches. Individuals whose activation threshold is too small to achieve world-view closure are at a reproductive disadvantage, and over time eliminated from the population. Eventually the proclivity for an ongoing stream of thought becomes so firmly entrenched that it takes devoted yogis years of meditation to even briefly arrest it. There is selective pressure for parents who monitor their child's progress in abstraction

and interact with the child in ways that promote the formation of new abstractions the next level up. Recall the discussion in section II.4 concerning the incorporation of new polymer species by supracritical autocatalytic sets. This kind of parental guidance is analogous to handcrafting new polymers to be readily integrated into a particular autocatalytic set; in effect it keeps the child's mind perpetually poised at a supracritical state. Language provides a means for individuals to mutually enrich one another's world-views, and to test their world-views against each other, and in so doing prompt one another to penetrate deeper and deeper into the onion.

49. Clearly social processes are an integral component of cultural evolution. In fact the origin of culture is often unquestioningly equated with onset of the capacity for social transmission. However, as many authors have pointed out (e.g. Darwin 1871; Plotkin 1988), although transmission is wide-spread in the animal kingdom, no other species has anything remotely approaching the complexity of human culture. Moreover, although in practice transmission plays an important role, is it crucial? If, for example, you were the only one human left on the planet, but you were able to live forever, would meme evolution grind to a halt? If you were to come up with some unique dance, would you not be exploring the space of possible dance memes even though no one was watching? If you found an ingenious way to fix a broken toaster, would you not still have invented a novel meme?

50. In biological evolution, transmission and replication go hand in hand; genetic information gets replicated and is transmitted to offspring. But that is not necessarily the only way of getting the job done. In memetic evolution, the most obvious means of meme replication is through social processes such as teaching or imitation, but there is a second form of replication that takes place within an individual. We noted earlier that in the mind of someone engaged in a stream of thought, each meme is a statistically similar variant of the one that preceded and prompted it. It is in this sense that they self-replicate without necessarily being transmitted to another host. Thus there need not necessarily be more than one individual for a meme to evolve. Nevertheless, although intra-individual meme replication is sufficient for evolving memes, the culture of a single individual would be extremely impoverished compared to that of a society of interacting individuals, because the number of memes increases exponentially as a function of the number of interacting memetic-level individuals. As a simple example, a single memetic individual who invents ten memes is stuck with just those ten memes. A society of ten interacting individuals, only one of whom has reached the memetic stage and can invent ten memes, is no better off; there are still just ten memes. In a society of ten noninteracting individuals, each of whom invents ten memes but does not share them, each individual still has only ten memes. But in a society where each of the ten interacting individuals invents ten memes and shares them, each individual ends up with one hundred memes. The bottom line is: culture as we know it, with its explosive array of meaningful gestures, languages, and artifacts, depends on both intra-individual and inter-individual meme replication.

51. In fact it is possible that cognitive closure as described above first occurred at the level of the group, within a collection of interacting individuals, and cognitive closure at the level of the individual came into existence some time later. (The two need not be mutually exclusive; it is possible that group-level closure could persist after the arrival of individual-level closure.)

IV. IMPLICATIONS

52. In this section we explore some implications of the autocatalytic cognition hypothesis. This is the most speculative section of what is admittedly a speculative paper.

IV.1 WHY DON'T ANIMALS EVOLVE CULTURE?

53. As noted in Section III.2, the penalty for having too low a neuron activation threshold is very high. Each meme has little relevance to the one that preceded it, and thinking is so garbled that survival tasks are not accomplished. On the other hand, too high a neuron activation threshold is not life-threatening. The focus is virtually always affected by external stimuli or internal drives, and memory is reserved for recalling how some goal was accomplished in the past. This may be the situation present in most brains on this planet, and though not harmful, it has its own drawbacks. A stream of thought dies out long before it produces something creative. However, this may not be of practical consequence to other species. The advantages of a stream of thought would largely be lost on nonhuman animals because they have neither the vocal apparatus nor the manual dexterity and freedom of upper limbs to implement creative ideas. (Language, for example, drastically increases the degrees of freedom of what can be expressed.) No matter how brilliant their thoughts were, it would be difficult to do something useful with them. Moreover, in an evolutionary line there is individual variation, so the lower the average activation threshold, the higher the fraction of individuals for which it is so low that they do not survive. It seems reasonable to suggest that animals are not prohibited from evolving complex cognition a priori, but that there is insufficient evolutionary pressure to tinker with the threshold until it achieves the requisite delicate balance to sustain a stream of thought, or to establish and refine the necessary feedback mechanisms to dynamically tune it to match to the degree of conceptual fluidity needed at any given instant. It may be that humans are the only species for which the benefits of this tinkering process have outweighed the risks.

IV.2 PSYCHOLOGICAL CONSIDERATIONS

54. Initially a child is expected to be unselective about meme acquisition, since (1) it does not know much about the world yet, so it has no basis for choosing, and (2) its parents have lived long enough to reproduce, so they must be doing something right. However, just as importing foreign plants can bring ecological disaster, the assimilation of a foreign meme can disrupt the established network of relationships amongst existing memes. Therefore the child develops mental censors that ward off internalization of potentially disruptive memes. Censors might also be erected when a meme is embarrassing or disturbing or threatening to the self-image (Minsky 1985). This could be accomplished by temporarily increasing the activation threshold so as to prematurely terminate the meme's assimilation into the world-view. Much as erecting a fence increases the probability that people will stay on either one side or the other, censorship warps the probability that a meme will partake in any particular stream of thought, such that the individual either avoids the censored meme or dwells on it excessively. (This seems to be consistent with our bipolar attitude toward highly censored subjects such as aggression and sexuality.) Thus censorship precludes incorporation of a meme into the autocatalytic portion of the memory, and thereby interferes with its holographic nature.

55. Categorization creates new lower-dimension memes, which makes the space denser, and increases susceptibility to the autocatalytic state. On the other hand, creating new memes by combining stored memes could interfere with the establishment of a sustained stream of thought by decreasing the modularity of the space, and thereby decreasing density. If cross-category blending indeed disrupts conceptual networking, one might expect it to be less evident in younger children than in older ones, and this expectation is born out experimentally (Karmiloff-Smith 1990). There is evidence of an analogous shift in human history from an emphasis on ritual and memorization toward an emphasis on innovation (Donald, 1991). As world-views become more complex, the artifacts we put into the world become more complex, which necessitates even more complex world-views, etc.; thus a positive feedback cycle sets in.

56. We mentioned that animals are hard-wired to respond appropriately to certain stimuli, as are humans. However, the ability of humans to develop world-views with which they can make decisions about what action to take may obviate the need for some of this hard-wiring. Genetic mutations that interfere with certain regions of hard-wiring may not be selected against, and may actually be selected for, because in the long run they promote the formation of concepts that generate the same responses but can be used in a more context-sensitive manner. However, this increases the amount of computation necessary to achieve a workable world-view.

IV.3 THE ROLE OF AUTOCATALYSIS IN EVOLUTIONARY PROCESSES

57. Returning briefly to the origin-of-life puzzle, recall that traditional attempts to explain how something as complex as a self-replicating entity could arise spontaneously entail the synchronization of a large number of vastly improbable events. Proponents of such explanations argue that the improbability of the mechanisms they propose does not invalidate them, because it only had to happen once; as soon as there was one self-replicating molecule, the rest could be copied from this template. However, Kauffman's theory that life arose through the self-organization of a set of autocatalytic polymers suggests that life might not be a fortunate chain of accidents but rather an expected event.

58. Although there is much evidence for this hypothesis, definitive proof that it is the correct explanation of how life originated will be hard to come by. However, if we are interested in the more general question of how information evolves, we now have another data point, another evolutionary process to figure into the picture. Culture, like biological life, is a system that evolves information through variation, selection and replication. In fact, it has two layers of replication, one embedded in the other, and to actualize the inner layer of replication, all members of the culture must establish their own personal world-view, which generates their own unique autonomous stream of sequentially activated self-similar patterns. Consistent with Kauffman's assertion that the bootstrapping of an evolutionary process is not an inherently improbable event, the "it only had to happen once" argument does not hold water here because the cultural analog of the origin of life takes place in the brain of every young child. Autocatalysis may well be the key to the origin of not only biological evolution, but any information-evolving process.

V. CONCLUSIONS

59. Cultural evolution presents a puzzle analogous to the origin of life: the origin of an internal model of the world that both generates and is generated by streams of self-sustained, internally driven thought. In this target article we have explored a plausible scenario for how cultural evolution, like biological evolution, could have originated in a phase transition to a self-organized web of catalytic relations between patterns. TABLE 1 presents a summary of how the components of the proposed theory of cultural autocatalysis map onto their biological counterparts.

EVOLUTIONARY SYSTEM	BIOLOGY	CULTURE
INFORMATION UNIT	Polymer Molecule	Meme
INTERACTION	Catalysis	Reminding, retrieval, Reconstruction
AUTOCATALYTIC SET	Catalytically closed set of polymer molecules; primitive organism	Network of inter-related memes; World-view
REPLICATION	Duplication of each molecule, segregation via budding	Correlation between consecutive memes; Social learning; teaching,
SELECTION	Physical constraints on molecules, affordances and limitations of environment	Associations, drives; social pressures, affordances and limitations of environment
VARIATION	Novel food molecules, nonspecificity of catalysis, replication error	Sensory novelty, blending; expressive constraints, misunderstanding, etc.

TABLE 1: Components of an autocatalytic theory of biological evolution and their cultural counterparts

60. The scenario outlined here is nascent. Putting the pieces together would require the cooperation of neuroscientists, developmental psychologists, cognitive scientists, sociologists, anthropologists, archeologists, and perhaps others. Nevertheless, I know of no other serious attempt to provide a functional account of how memetic evolution got started. Whether or not the scenario outlined here turns out to be precisely correct, my hope is that it draws attention to the problem of cultural origins, suggests what a solution might look like, and provides a concrete example of how we gain a new perspective on cognition by viewing it as an architecture that has been sculpted to support a second evolutionary process, that of culture.

ACKNOWLEDGEMENTS

I would like to thank David Chalmers, Merlin Donald, Bruce Edmonds, Harold Edwards, Stuart Kauffman, Francis Heylighen, Norman Johnson, Wolfgang Klimesch, William Macready, and Mario Vaneechoutte for helpful discussion and comments on the manuscript.

FOOTNOTES

1. Although this may not be completely accurate; see Donald (1993) and accompanying commentary.
2. This number is perhaps better appreciated when we realize that its magnitude is 10,300
3. In a reducing atmosphere there is no free oxygen present. The presence of ferrous (FeO) rather ferric (Fe₂O₃) iron in primitive rock leads us to believe that the earth's atmosphere was reducing when life began. (It is no longer so today.)
4. See Kauffman (1993) for an interesting discussion of why error catastrophe becomes a serious problem as the parts of the system becomes more co-adapted.
5. The niche it filled still exists, so there is still selective pressure for it to evolve all over again. But the information has to re-evolve (as opposed to being retrieved from storage).

Of The

The Meme Machine

Susan Blackmore

Oxford: Oxford University Press, 1999, Cloth: ISBN 0-19-850365-2

The Meme Machine follows through on Dawkins' (1976) fascinating suggestion that culture, like biology, evolves through the processes of variation, selection, and replication. *TMM* does a nice job of laying out the basic idea - that, much as organic life evolves into more complex forms through progressive adaptation to environmental constraints, ideas and artifacts build on what came before in response to the necessities of human survival. Like Richard Brodie's (1996) *Virus of the Mind*, and Aaron Lynch's (1996) *Thought Contagion*, *TMM* explores how this kind of evolutionary perspective on culture can shed light on various aspects of the human experience, such as why we talk so much, believe in alien abduction and fantasize about sex. (Though the chapter titled 'An orgasm saved my life' never gets around to explaining how an orgasm saved someone's life.)

Is Imitation What Distinguishes Humans From Animals?

TMM is about imitation rather than innovation. Blackmore lays this out explicitly: "The thesis of this book is that what makes us different is our ability to imitate." (p. 3). The story goes: humans can imitate, and animals cannot, and that is why we alone have evolved culture. The idea that conformity, not creativity, is the hallmark of the human condition, will inevitably strike some readers as so unappealing and counter-intuitive, that they won't get past Chapter One. And in the end, the case she makes may not be convincing. Nevertheless, the possibility is at least worth considering, and it is interesting to see how it fares.

Blackmore begins by arguing that imitation is natural and ubiquitous in humans, but almost non-existent in animals. Though the first part of this argument is clearly true, the second is highly controversial. As it turns out, while the book was being written, the consensus was swinging in favor of the view that animals *do* imitate. (An article by Byrne and Russon 1998 and the accompanying commentary, provide an insightful review of this topic.) Despite the fact that animal culture is impoverished at best, they do appear to have some imitative capacity. So from the outset, there are doubts as to whether Blackmore will succeed in pulling her 'imitation drives culture' thesis off, but the reader doesn't know for sure.

The next few chapters spell out how memes function as replicators, and discusses how the world looks from the 'meme's eye view' (Dennett 1995). The 'imitation drives culture' hypothesis leads Blackmore to circumscribe what counts as a meme and can be culturally transmitted. For

example, she limits the transmission process to imitation of one human by another. If a child learns to peel a banana by watching her mother, a meme has replicated, but if the child learns this skill from a cartoon character on television, no replication has taken place. By the end of the book (particularly in the chapter on the internet) she relaxes this claim somewhat. Human-made artifacts now seem to play a role in her vision, though elements of the natural world still don't. Thus if a child figures out how to peel a banana by watching the petals of a flower unfold, her flower-inspired 'how to peel a banana' meme is *not* transmittable. In the blink of an eye, Blackmore discards the possibility that *any* experience can be food for thought and thus food for culture, on the on the grounds that it is "extremely confusing" (p. 45). The worldview implied by the Shroödinger equation is extremely confusing too, but its batting average as a predictor of experimental outcomes is unsurpassed. 'Confusing' is not synonymous with 'wrong'.

Blackmore also claims that "perceptions and emotions are not memes because they are ours alone and we may never pass them on." (p. 15). It follows that the feeling evoked by a painting depicting a stormy night at sea has no relationship to what the artist was feeling at the time ... that a teacher's attitude of compassion has no impact on the cultural dynamics of the classroom. Thus it isn't certain how Blackmore's narrow definition of meme clears up the confusion.

The Origin of Culture

Chapter Six focuses on the dramatic increase in brain size that began two and a half million years ago during the transition from *Australopithecus* to *Homo*. It is here that hopes of pulling off the 'imitation drives culture' thesis take a nosedive. Blackmore correctly notes that the archaeological record reveals a sudden *increase* in tool variety at this time. She does not seem to be aware that this contradicts the thesis of her book. That is, if imitation were the bottleneck to culture, then prior to the origin of culture there would have been variation everywhere, and the onset of imitation would have funneled this variation in a few of the most useful directions. To bolster the thesis that imitation is the cultural bottleneck with archaeological evidence, Blackmore would have had to find a period of time where tool variety sharply *decreased*.

The evidence she cites is, in fact, consistent with the thesis that creativity, rather than imitation, was the bottleneck to culture. The lack of cultural complexity in animals - despite the evidence that they can imitate when put to the test - is also consistent with this proposal. Imitative capacity remains latent or hidden until there is variation for it to work on. In 'Meme and Variations', my computer model of cultural evolution, when I set the agents' ability to imitate to 1 and their ability to invent to 0, what happened is ... nothing (Gabora 1995). There has to be something worth imitating before the ability to imitate will manifest itself. Novelty can then breed more novelty. Or as one choreographer (whose name I forget) put it: "If we don't do what our predecessors did, we're doing what our predecessors did."

The material that follows, dealing with the relationship of memetics to language and various social issues such as beauty and birth control, is well done. It provides a wealth of intriguing alternatives to explanations offered by sociobiology and evolutionary psychology over the last few decades. Sharpening the contrast between these approaches - for example, contrasting the memetic explanation for gossip with that proposed by Barkow (1992) - would have made this part of the book even more valuable.

Memetics and Profound Stuff

Like Dawkins, Dennett, Brodie and Lynch, Blackmore cannot resist going to great lengths to convince us that religion and the New Age movement are nothing but hotbeds of manipulative tricks. "Religions build theories about the world and then prevent them being tested. Religions provide nice, appealing and comforting ideas and cloak them in a mask of 'truth, beauty, and goodness'. The theories can then thrive despite being untrue, ugly, or cruel ... I do defend the idea that science, at its best, is more truthful than religion." (p. 202-3). One can't help but wonder here 'What about religion *at its best*? Didn't religion give birth to science?' I for one am getting bored with this kind of thing. Those who devote their lives to religion may similarly deride science and gloat over how concepts such as 'fallen from grace' and 'purification of the soul' are vastly more meaningful than concepts like 'Turing test', and 'corpus callosum'. Instead of pitting one against the other, it would have been more satisfying to hear about how different experiences open up different memetic niches, which in turn generate different experiences, i.e. the 'embryology' of the process by which a mind incorporates a given memplex. I'd like to hear what is going on when a meme (whether it be 'evolution' or 'human redemption') percolates far into a conceptual network touching every meme it encounters, resulting in a more consistent or satisfying worldview. In fact there is some disparity between the 'science rules' attitude and the relative paucity of theory or data. If the title leads you to expect material on computer models, cognitive science, complexity, information theory, etc. you might be disappointed. There isn't a lot on the workings of the memetic machinery.

From there the book moves onto topics like consciousness, the meaning of life and the concept of self. Much of this is intriguing; for example, the cross-cultural comparison of near death experiences. However to define the 'self' as "a bunch of memes" (p. 231) is misleading (particularly if emotions and attitudes don't count as memes!) It's like saying a chair is just a bunch of sticks. Much as 'chairness' resides in the way sticks are organized, the self arises from the way memes are structured and interact with one another, something about which Blackmore could have said more.

Is Memetics a Second Form of Evolution or Just an Analogy?

Blackmore does not feel obliged to dig her spurs too deep into evolutionary theory, on the grounds that borrowing concepts from biology can lead cultural theorists astray: "There need be no memetic equivalent of the phenotype or the vehicle, any more than there are equivalents for strictly genetic concepts like alleles, loci, mitosis, and meiosis." (p. 66). Repeatedly she insists "We must remember they are only analogies." (p. 42) However, this stance also discourages potentially fruitful directions. Consider what happens when someone familiar with the concept of snow skiing first hears of water skiing. He might continue to include 'snow' as vital to the concept of 'skiing', and view water skiing as *analogous* to skiing. Or he might generalize the definition of 'skiing' to include both snow skiing and water skiing. Neither is objectively more *correct*, but the generalized concept of skiing more readily invites the application of knowledge gained through the study of snow skiing to water skiing. This is not equivalent to saying that water skiing *is* snow skiing; it's just a way of organizing world knowledge that is less likely to waste time by reinventing the wheel. Let us suppose that, a few years before water skis hit the market, you had been a venture capitalist, and were approached by two inventors who had both

come up with the idea of water skis. One inventor had spent the last few years working for a company that makes snow skis, and talked at length about how the length and width of a ski affect glide and balance, why skis curl up at the tip, etc. The other knew little about snow skis and argued this didn't matter because snow and water are not the same thing, it's "just an analogy". Which inventor would you have been more likely to fund?

Similarly, we can either say that DNA, chromosomes, etc. are vital components of evolution, and memetic change is *analogous* to evolution, or we can redefine evolution as any process wherein the iterated variation and selection of information induces adaptation to environmental constraint, and view memetic change as a second form of evolution. In so doing, one finds that concepts such as fitness, epistasis, drift, mutation, morphology, niches and attractors provide an extremely useful scaffold upon which to investigate how ideas unfold as they are assimilated by one individual after another and this scaffold gives the ideas their own unique slant. (See Radnitzky and Bartley 1987 and Hull 1988a, 1988b.)

The example Blackmore provides to illustrate how biological concepts can mislead is the distinction between genotype and phenotype. Most memeticists maintain that something along these lines is useful; i.e. there is a need to differentiate between the mental representation of a meme in the mind, and the implementation of it as behavior, vocalization or artifact. Blackmore argues that this distinction does not account for the difference between copying the result (as when someone watches you make soup and then makes it themselves) and copying the instruction (as when you give someone a recipe for soup). In fact, this raises no problem at all for the genotype/phenotype distinction. Both soup and recipe are artifacts, phenotypic expressions of different but related mental representations. As one's understanding of biological concepts increases, the danger of misapplying them decreases.

The exception to Blackmore's avoidance of biological concepts are the two chapters on memetic altruism. The idea that not only genes, but memes, impel us to behave altruistically toward others who bear copies of them, is a promising answer to a problem that has plagued sociobiology for some time. Blackmore does a good job of explaining the concept, though it would have been appropriate to mention that it has been around for some time (Heylighen 1992, 1992, Gabora 1996, 1997, 1998a, Evers 1998).

Wrapping Up

I was not convinced of the pivotal role given to imitation, but you may well be. I am perhaps not the most objective of readers. First, because I harbour some possibly overly-idealistic memes about the human condition. And second because my own research supports the alternative proposition that creativity was the bottleneck to culture. A story can be told. Whereas biological creativity is random and 'breadth-first' - i.e. generate as many variants as possible and hopefully one of them will do the trick - cultural creativity is non-random and 'depth-first' - i.e. generate novelty *strategically*, using knowledge of relationships (Gabora, 1996, 1997). For a mind to be capable of strategic creativity, its initially discrete memories and stimulus-response associations must transform into an interconnected conceptual web, or worldview, wherein related concepts are connected by way of abstractions. In Gabora (1998b), I demonstrate how an interconnected

worldview could emerge through an autocatalytic process instigated by a genetic mutation which lead to decreased neuron activation threshold.

TMM is worth taking a look at. The issues it addresses are big and important, and memetics offers some compelling answers. Readers should be aware, though, that many of the ideas Blackmore discusses are better developed in other scholarly work in memetics, which often goes uncited here. Blackmore adds her own wrinkles, but she is not quite as alone out there on the wild, dangerous frontiers of human inquiry as the book might suggest.

If we accept the premise that memes evolve, let's use everything we've got and see if memetics has the potential to do for the cognitive and social sciences what the theory of natural selection has done for biology. *The Meme Machine* is a start. It is not inconceivable that the next century will bring forth more books on cultural evolution than this century has on biological evolution.

MACROMEMETICS: TOWARDS A FRAMEWORK FOR THE RE-UNIFICATION OF PHILOSOPHY

By

Derek Gatherer

School of Biomolecular Science,
Liverpool John Moores University,
Byrom St., Liverpool, L3 3AF. UK.

Abstract

The review of the philosophical and scientific antecedents of memetics by Elan Moritz [27] is extended to cover 20th century philosophy. It is proposed that '*macromemetics*', i.e., the study of the evolution of entire meme pools, is in many respects a similar enterprise to that attempted by the cultural evolutionist school of anthropology which flourished in the late 19th and early 20th centuries. Memetics may provide a new, and more rigorously Darwinian, slant to this rather neglected branch of anthropology. Furthermore, it is proposed that much of the terminology and conceptual apparatus of memetics may be reconciled with that used by recent Continental philosophers in their studies of culture, thus suggesting a possible Darwinian framework for the re-unification of Western philosophy.

Key words: meme, culture, evolution, Structuralism, philosophy, reductionism, anthropology, civilization.

1 Introduction and Summary

This article reviews the divided state of Western Philosophy, and points out certain areas in which the Continental and Anglo-American schools may be reconciled by the use of a memetic approach. Firstly, the similarities between Popper's hierarchical dissection of his *World 3* concept and the hierarchical nature of the gene/meme analogy are discussed. Special attention is paid to the lowest level, that of fundamental propositions or memetic '*nucleotides*', and the highest level, that of the meme pool. The study of meme pool evolution is compared with the cultural evolutionary school of social anthropology. Additionally, incipient memetical ideas are detected and examined in the work of Peirce, Saussure, Wittgenstein, Toynbee, Foucault and Derrida. The principal conclusion is that wherever philosophy is concerned with informational entities, a memetical approach may be applied. Both the cultural subject matter of Continental philosophy and the logical and linguistic concerns of the Anglo-American tradition can be re-expressed memetically. Memetics thus provides some possible common ground for the reunification of the two traditions.

2 Western Philosophy Divided

Since the time of Immanuel Kant (1724-1804), Western philosophy has been split into two main traditions, namely Continental philosophy which took its lead from J.G. Fichte (1762-1814) and developed via G.W.F. Hegel (1770-1831) and Karl Marx (1818-1883) into 20th century

Existentialism and Structuralism, and secondly Anglo-American philosophy which continued the radical empiricist tradition of David Hume (1711-1776) as developed by Bertrand Russell (1872-1970). The labels *Continental* and *Anglo-American* are unfortunate in that they imply some kind of geographical separation of the two traditions. While this is true to a certain degree, many of the principal figures in the Anglo-American tradition have been native German-speakers, such as Ludwig Wittgenstein (1889-1951), Karl Popper (1902-1994) and the various members of the Vienna circle. Conversely, Continental philosophy is now increasingly popular in Britain and the USA, although usually in academic departments of literature and cultural studies rather than those of philosophy (concise reviews of the two traditions are provided by Scruton [40] and Pears & Kenny [29]).

Anglo-American philosophy primarily concerns itself with logic, philosophy of science and linguistic analysis of meaning. Continental philosophy, on the other hand, is interested in politics, aesthetics, culture and *'mind'*, all topics generally regarded as too diffuse and intangible for the more logic- and science-oriented Anglo-Americans. In recent years a certain cross-fertilization has taken place, with Wittgenstein's later work being of influence in both main branches [51]. Additionally, with the development of what is known as Cognitive Science, the subject of *'mind'* and consciousness is becoming respectable again in the Anglo-American philosophical world (reviewed by Gardner [17]).

The principal thesis of this essay is that memetics, being applicable to all transmitted information whether scientific or more generally cultural, provides a means for reuniting Western philosophy. Many of the concerns of Continental philosophers, such as the state of society and social change, are approachable using memetics, and much of their terminology and conceptual framework can be re-expressed in memetic terms. This is not so unlikely as one might initially suspect, since the roots of Structuralism are in 19th century cultural evolutionism. Before dealing with this proposal in more detail, some consideration will be given to the meme-gene analogy and its relevance to the subject of *'culture'*.

3 The Hierarchical Structure of the Meme Pool and Popper's World 3

Memes are not transmitted independently. A religious education, for instance, imparts an enormous bundle of memes to an individual which are generally delivered all together or not at all. They are, to borrow from genetic terminology, *'linked'*. Indeed many of these memes may be dependent on each other (in what Speel [41] has termed a *'memeplex'*). The process of growing up and living in a certain culture at a certain time means that an individual is very likely to share a vast quantity of memes with other individuals in the same circumstances. This is what may be termed the meme pool of that group or society. Where a society is highly pluralistic, several meme pools may coexist and partially overlap. Unlike higher eukaryotic gene pools [52], meme pools are not closed systems between which absolutely no interaction can take place. The Roman Empire, for instance, played host to a vast plethora of cultures and religions. Much meme flow between diverse meme pools took place; for instance the interaction between Greek and Jewish thought which produced the work of Philo of Alexandria (c. 30 BCE - 40 CE) and had a seminal influence on early Christianity. However, despite this extensive interaction the Jewish and Hellenistic meme pools remained sufficiently different to be clearly recognizable as distinct cultures. Although this cultural diversity was reduced in the Middle Ages, Christianity was

regularly riven with heresies and schisms even before the Reformation. Memetic mutation and recombination, like their genetic analogues, are omnipresent features of meme pools. Nevertheless, the tendency of memes to be transmitted en bloc rather than as an independent assortment, suggests that we are justified in regarding the meme pool as a useful concept. A more difficult question is how to subdivide the meme pool.

Dawkins [9] cites the work of Karl Popper as one of his inspirations for the meme concept. Popper [34, 36] introduced the term *'World 3'* to refer to the objective contents of thought. His discussion of these contents is almost identical to Dawkins' presentation of examples of memes.

Compare Dawkins' original definition:

'Examples of memes are tunes, ideas, catch-phrases, clothes fashions, ways of making pots or of building arches'[9],

with Popper's definition of World 3:

'theoretical systems.... problems and problem situations.... critical arguments..... the contents of journals, books and libraries' ([34], p. 107).

It is clear from this that Popper and Dawkins have similar concepts in mind. Although Popper's first three specific examples could be grouped under the heading of Dawkins' third example i.e. *'ideas'*, his inclusion of printed artifacts such as the contents of libraries demonstrates that Popper, like Dawkins, also wishes to include the physical manifestations of transmitted information in his definition. In other words, both authors fail to make a clear distinction between what Speel [42] terms the memotype and the phenotype. Popper also intends that World 3 should include all objective thought contents both past and present. Concepts evolve in World 3 just as genes evolve in World 1, but World 3 does not itself evolve. Meme pools are collections of memes available to human populations at points in space and time, and they therefore evolve, diversify, go extinct etc. World 3 may thus be regarded as the set of all meme pools, possible and actual. However, the point in this instance is that the contents of meme pools correspond to the contents of World 3, and that both may be hierarchically structured (Popper [35]). This process strengthens the meme/gene analogy and eliminates the possible criticism that memes are difficult to define precisely, since genes are also non-discrete elements arranged hierarchically in the genome.

The lowest and most fundamental level is that of simple propositions. These will be shared by almost all the higher level structures. For instance, some propositions of logic may fall into this category. Higher level memetic structures such as religions or science or political beliefs may be widely different, or even incompatible, but are often based on the same simple propositions. Despite the uneasy relationship between Christianity and science over the last 400 years, a case can be made that both are derivatives of Platonism. They share what Peter van Inwagen [46] has called the Common Western Metaphysic. A further injection of ancient Greek thought into Christianity was provided by Thomas Aquinas (1224-1274) who reintroduced Aristotelian logic. Indian philosophy, by contrast, has its own system of logic known as Nyaya (Phillips [32]), and a metaphysical structure that is quite different to the Western Metaphysic outlined by

van Inwagen [46]. A little more will be said later about the Logical Atomist school of Anglo-American philosophy for whom the simple propositions of Western logic were the main topic of study. However, at present it will suffice, following Popper, to regard fundamental propositions as the primary basis of any higher level memetic structures. In the gene-meme analogy they are the memetic '*nucleotides*'. Most strands of Western thought, whatever their differences at more complex levels, have a common basis at this lowest '*nucleotide*' level.

Popper is less specific about the intermediate levels of his hierarchy but envisages a progressive building upwards to '*complex ideas*'. This would presumably include entities like scientific theories, specific religious doctrines or points of political dogma. These complex memes have many component parts, and may stand alone, but are at their most effective when combined with other complex memes. For example, Einstein's Special Theory of Relativity is a robust meme which may be transmitted alone, but will generally be replicated more accurately (and possibly also more efficiently) if when delivered as part of a general education in physics including other complex memes such as Maxwell's Equations and the Copenhagen Interpretation.

Above the level of the complex meme - which may perhaps be analogous to the gene as a functional, possibly '*selfish*', but not strictly independent unit - we have co-transmitted aggregates of memes. Examples of these might include religions, scientific disciplines or artistic schools considered as wholes. These are what might be termed the '*linkage groups*' of memetics or '*memeplexes*' (Speel [41]).

Finally we arrive at the total meme pool, or World 3. As emphasized above, Popper's choice of the word '*World*' is appropriate in that he wishes to include every single content of objective thought. There is only one World 3. On the other hand, meme pools exist in the plural, being more analogous to the gene pools of biology in that they may be permanently separate, or at most in intermittent communication, and located at varying points in time and space. Since in a biological context, gene pools correspond roughly to species, or at least to sub-species or incipient species, it is here proposed that meme pools are the appropriate species-level entity in a memetic context. This is contrary to Benzon [3] who sees '*paradigms*' as the species-level memetic entity. If the meme pool/species equivalence is maintained, then paradigms are closer to gene-level entities, like Popper's '*complex ideas*' discussed above. Although meme pools are not completely isolated in the way that higher eukaryotic gene pools are, the analogy is still acceptable if one thinks of prokaryotic gene pools where much horizontal transfer of genetic information takes place (Speel [42]).

3.1 Meme pools and the total cultural apparatus of societies

A unanimously acceptable definition of '*culture*' has always been difficult to obtain (see the review by White [47] for a history of the controversy). Two broad strands of opinion may be identified; those that believe that culture is what people think, do and produce, and most importantly see culture as a learned and retransmitted entity (Leach [24] p. 9), and in contrast those who see it as primarily an advanced biological adaptation to the environment. The latter school has recently been strengthened by support from sociobiologists (Wilson [49]). Although this is a major controversy in anthropology, from the point of view of memetics it is perhaps not necessary to reach a final decision in favour of one view over the other. Sociobiologists see

culture as the product of selection on behaviour, but that the primary consequences of that selection are genetic, and only secondarily memetic. For sociobiologists, culture is only likely to be efficiently replicated when the appropriate genetic basis is already there. For instance, a sociobiologist might point out that belief in the undesirability of incest may stem ultimately from the undesirable medical consequences of inbreeding. Those who are genetically predisposed to avoid incest (e.g. through genetically influenced feelings of disgust) may do so highly efficiently, and thus raise less inbred and consequently healthier children to whom they will also pass their incest-avoidance genes. Incest avoidance is an almost (but not quite, eg. ancient Egypt - Hopkins [19]) universal feature of human societies, which tends to support the opinion that it is an adaptation with an ultimately genetic origin. However, the resulting behaviour of incest avoidance may still be treated as a meme, i.e., one may learn an incest taboo from a person who genetically avoids incest, even though one may not be oneself genetically predisposed to avoid incest. The incest avoidance meme is also subject to selection, and will spread if incest avoidance produces healthier progeny who then learn incest avoidance themselves. The question of learning versus sociobiology thus seems to lose some of its difficulty when viewed from a memetical standpoint.

Conversely, ideas, like genes, that are maladaptive to individuals may still spread within populations. Incest avoidance memes, like incest avoidance genes, increase the fertility of those who carry them, but suicide cults are obviously highly counter-adaptive to the individuals who sacrifice their lives under their influence. However, a suicide cult meme may procure an advantage to the culture in which it occurs, where the incidence of such suicide is tightly culturally controlled. For example, kamikaze fighter pilots were a formidable military weapon for early-modern Japanese culture. On the other hand, the James Jones mass suicide in Guyana was a unique event which eliminated the entire culture in which it occurred. A genetic predisposition to suicide may exist (possibly associated with some genetic form of depressive illness), but suicidal behaviour may also be learned by indoctrination. Thus, both adaptive and maladaptive behaviours may be considered as selectable memes, whether or not there is also a genetic basis. Genetics has also traditionally focused, until very recently, on the individual as the unit of selection. Part of the appeal of memetics is its compatibility with gene-centred models of selection (Dawkins [9], Williams [48]). Focusing on the spread of memes permits explanation of behaviours which are maladaptive to the individual.

In summary, the traditional divide between culture-as-transmitted-information and culture-as-advanced-adaptation may not be so serious, if transmitted information is also subject to selection. Nature versus nurture debates of the past generally relied on the assumption that only nature was subject to Darwinian selection. Nurture, i.e. transmitted information, was generally regarded as being independent of external forces, a pure product of human superstition and/or rationality, or alternatively subject to dialectics of a Hegelian or Marxist variety. Memetics, by positing a strictly Darwinian process for nurture, thus questions the division between environment and biology, since both are evolving under the same dynamic.

Meme pools may exist in isolation for thousands of years, as was the case for many of the indigenous peoples of the globe before the European expansion beginning in the late 15th century. As Benzion [3] has illustrated, the isolation of early migratory groups of humans would have resulted in both genetic and cultural divergence, by both genetic/memetic drift and selection

for adaptation to local conditions. As the globe became more populated, isolated meme pools regained contact. When Christopher Columbus stepped ashore at Watling Island in 1492, contact was established between two meme pools whose nearest common ancestor was at least some 12,000 years in the past. New meme pools may result from the contact of previously isolated ones, or one meme pool may virtually swamp and displace another, as was the case in the Americas in the aftermath of Columbus. Much anthropological investigation has been carried out in 'acculturation', i.e. the consequences of culture contact, usually between an indigenous society and a Western colonising power (Beattie [2] p. 241). If memetics is to be of any value for the study of society as a whole, it is important to judge to what extent memetic phenomena may be seen at work at the level of the meme pool. This is not likely to be an easy task: macroevolution is still the most challenging problem of biological evolutionary theory, and is exacerbated by the fact that macroevolutionists are limited to observation rather than experimentation (Stanley [44]). Fortunately for would-be '*macromemeticists*', much study has already been devoted to evolution of cultures as wholes. Unfortunately, much of that work is by now rather old and somewhat out of favour. Nevertheless, a reassessment from a memetic point of view is desirable.

4 The Cultural Evolutionary School of Social Anthropology

In 1786, Sir William Jones reported the results of his comparative studies in the Sanskrit, Latin and ancient Greek languages. His conclusion was that all three were descended from a common progenitor (Gardner [17] p. 196). This primitive phylogeny of the Indo-European languages was one of the first strands of evidence for any kind of evolutionary process, and was a factor which profoundly influenced Darwin:

'We find in distinct languages striking homologies due to community of descent, and analogies due to a similar process of formation' (Darwin 1871, quoted by Dennett [11]).

The study of cultural evolution was thus technically a predecessor of that of biological evolution, but fell behind in the following century and a half.

Darwin's contemporary, Herbert Spencer (1820-1903), was the first to take an evolutionary view of society as a whole, seeing it as progressing through various stages with Victorian English civilisation rather suspiciously at the pinnacle [43]. Unfortunately, in the hands of his lesser successors, Spencer's ideas deteriorated into a pseudo-scientific justification for imperialist exploitation of '*inferior*' societies (rev. by Dobzhansky [15]). Spencer, like Darwin, had a broad view of evolution as primarily a result of natural selection on naturally occurring variation producing gradual and progressive change. Those anthropologists who adopted the evolutionary theory of culture also took the gradualist line. One of the first of these was Lewis Morgan (1818-1881), who set out an evolutionary theory of society with three stages, namely savagery, barbarism and civilisation, which he posited as corresponding to the evolution of one species from another (Beattie [2] p. 6). Just as Darwin had concerned himself with the origin of species, so were the evolutionary anthropologists concerned with the origin of civilisation.

A remarkable pioneer was Edward Burnett Tylor (1832-1917) who was the first to use the comparative method. Preparing a database of customs, practices and beliefs and subjecting them to statistical analyses, Tylor's '*social arithmetic*' sounds like a premonition of the reductionist

approach of memetics ([25] p. 23). Tylor (1871, quoted by Leach ([24] pp. 38-39)) defines his field of study as follows:

'...that complex whole which includes knowledge, belief, art, morals, law, custom, and any other capabilities acquired by man as a member of society.....the first step in the study of civilisation is to dissect into details, and classify these into their proper groups.'

Tylor's use of the word 'acquired' demonstrates that he was interested in all that was transmitted and copied. The 'proper groups' into which he sought to break down this transmitted information include:

'weapons, textile arts, myths, rites and ceremonies.....laws of marriage and property.....special moral and religious doctrines' (Leach [24] p. 39).

Tylor is in the same subject area as memetics and approaches it in the same reductionist spirit. He even sketches an idea of memetic linkage in his concept of '*adhesion*', ie. identification of those cultural traits which tends to be co-transmitted, even in different cultures (Gardner [17] p. 228). Tylor's only deficiency is the absence of a neo-Darwinian technique with which to study the evolution of culture, which of course was not available at that time.

By the early 20th century the cultural evolutionists had split into two schools, those which saw the development of civilisation as an inevitable progression from a less civilised state which had occurred many times at different locations, and the '*diffusionists*' who put forward the idea of civilisation having originated once in ancient Egypt and radiating out from there (Kuper [23] p. 3). In more neo-Darwinian terms they differed on the question of whether civilisation was polyphyletic or monophyletic. There seems no a priori reason from a memetic point of view to prefer either opinion, but archaeological evidence has resolved the debate against the diffusionists.

The major anthropological theorist at the turn of the century was James Frazer (1854-1941) whose work, *The Golden Bough*, published in several volumes from 1890 onwards, was a grand synthesis searching for regularities or general laws in cultural evolution. Despite the immense arsenal of examples that Frazer brought to bear on the question, the eventual general consensus was that he had failed, and ever since then one influential strand of social anthropology has sought to deny that anything approximating to general laws may be found in the subject (Beattie [2] p. 44). Memetics holds out some fresh hope that a general body of laws capable of explaining social change may be found, and that that body is already with us, namely Neo-Darwinian theory applied to informational transmission.

Cultural evolutionism did not quite die in the aftermath of Frazer, but persisted to a certain extent in the work of Bronislaw Malinowski (1884-1942), Alfred Radcliffe-Brown (1881-1955) and Emile Durkheim (1858-1917). These thinkers tended to see societies as organic wholes, a view often referred to (not always congenially) as '*functionalism*'. Whereas the memetic approach sees societies as meme pools, the functionalist metaphor was more that of a physiological system. Cultural components of societies were seen as the organs of a body rather than as memes under selection (Mair [25] p. 36). One of the adverse consequences of this was the tendency to see

societies as balanced homeostatic entities which played down the process of change ([2] pp. 56-59).

It should not be thought that modern anthropology is totally adverse to the concept of memetics. Anthropologists have devoted a great deal of time to understanding the belief basis of culture, which is ideal material for memetic analysis. For example, much study has been carried out into the potlatch, a custom of the Kwakiutl people of Canada's western seaboard. The potlatch involves the conspicuous consumption, and occasionally destruction, of wealth and the products of labour (Beattie [2] p. 198). Even more extreme examples have been identified by anthropologists. For instance, in 1856 the Xhosa nation of southern Africa, under great pressure from European encroachment, came under the influence of a prophet who ordered them to destroy food stocks and cattle. Many starved to death as a consequence (Beattie [2] p. 263). The anthropological literature also provides interesting examples of other phenomena of memetic relevance. One interesting instance is the rapid spread of the Ghost Dance religion among the Plains Indians in the late 1890s. The Plains Indian culture was itself a fairly recent development which resulted from the westward retreat of the indigenous peoples of the eastern seaboard of the USA from the process of European colonisation. New meme pools were created as previously isolated tribes banded together in new political and social units. Interestingly, the Navajo people who were indigenous to the mid-West and, unlike the Plains tribes, were not a new and transient cultural entity, were completely resistant to the Ghost Dance religion and apparently much amused by it (Beattie [2] p. 261). The Ghost Dance illustrates how societies of diverse memetic origin and subject to intense pressures may evolve memetically in unpredictable and sudden ways. The Navajo, by contrast, were more memetically homogeneous and under less pressure from the European colonists. Another example which was consequent on the contact of previously isolated meme pools with colonial powers was the so-called '*cargo cult*' of Melanesia which spread rapidly throughout the region in the early 20th century.

These examples illustrate how complex memetic analysis may become. Claude Levi-Strauss refers to '*la pensee sauvage*' or '*mytho-logics*', implying that the memetic constitution of a culture may have virtually nothing in common with our own Western meme pool. Exactly what constitutes the basis of our meme pool can be found in the work of Peter van Inwagen [46], who has deduced a '*Common Western Metaphysic*', a set of assumptions agreed upon by all Western thought, whether religious or scientific. The phrase '*mytho-logics*' is used to imply that even the rules of logic, the memetic nucleotides alluded to earlier in this article, may be different in non-Western societies. The logic is mythical. Other anthropologists do not take such an extreme view but nevertheless are prone to make much reference to Wittgenstein's arguments about '*language games*' and '*family resemblances*' (Leach [24], Wittgenstein [51]). Wittgenstein will be dealt with further in the section on philosophy. Levi-Strauss's conclusions, although tremendously influential, are by no means undisputed. Lucien Levy-Bruhl was a forerunner of Levi-Strauss in his idea that primitive societies had fundamentally different systems of reasoning to their Western counterparts, but had abandoned this view by the end of his life (Gardner [17] pp. 223-259).

The fact that modern anthropologists have occasionally thought along lines that have brought them very close to what we would now term memetics is illustrated by White [47]. Writing about a definition of culture in a purely anthropological context, White postulates the unit of culture to

be a *'symbolate'*, which is defined as *'a thing or event dependent on symboling'*. Symbolates produce both *'somatic'* culture (ie. beliefs, behaviour, rituals, customs etc.), and *'exosomatic'* culture (i.e. artifacts, buildings, clothing, machines etc.). The symbolate thus corresponds quite well to Dawkins' definition of the meme as including *'ways of making pots or building arches'*, as well as beliefs, religion etc. The reason why White's system, like that of his proto-memetical predecessor Tylor mentioned above, does not quite correspond to memetics is that no explicit reference to selection or evolution of symbolates is made. However, in his reference to somatic and exosomatic symbolates, White provides categories which correspond to the phenotype and the memotype (Speel [42]).

4.1 Evolutionary Analysis of Civilisations

Anthropology tends to deal with indigenous peoples who have no written history. Where written records are available, the historian takes over. Some historians have seen patterns in the rise and fall of civilisations that are interpretable in memetic evolutionary terms. The most prominent exponents of this approach have been Oswald Spengler (1880-1936) and Arnold Toynbee (1889-1976). Toynbee's vocabulary is explicitly biological, with words like *'species'*, *'genus'* and *'mutation'* regularly utilised, albeit in a somewhat loose manner. If a civilisation can be seen as analogous to a large, sophisticated meme pool, then, like the gene pools of biological species, civilisations may speciate, evolve directionally in response to selection, or go extinct. Toynbee [45] identified 34 civilisations of which he regarded 15 as being still in existence. It is notable that Toynbee gives a great deal of prominence to ideology as a defining characteristic, thus suggesting strong parallels between his definition of separate civilisations and the concept of the meme pool. The lifetime of civilisations may be short - for instance the Minoan civilisation of Crete only lasted about 6 centuries from 2000 BCE to 1400 BCE - or very long - such as the Mayan civilisation of the Yucatan which may have lasted as long as 43 centuries from about 2500 BCE to its final destruction by the Spanish in 1680 CE. Just as no species is immortal, so it appears that civilisations also have a finite lifetime, after which memetic resources are exhausted and, if no *'speciation'* has taken place, extinction is the result. A more sudden extinction may be the consequence of a genocidal obliteration of meme pools by rival civilisations.

As far as *'speciation'* is concerned, Toynbee regarded some civilisations as derivatives of others. For instance, he posited that the Sumeric civilisation of the Euphrates-Tigris Delta gave rise to the Babylonian civilisation between 1700 and 1500 BCE. The Babylonian civilisation was abruptly terminated in 538 BCE at the destruction of Babylon by the Medes and Persians. However, the meme pool of Babylonian civilisation left a potent memetic residue in the form of astrology, which survives to a certain extent even today (much to the dismay of scientists). An earlier offshoot of the Sumeric civilisation was the Indic civilisation of northern India which survived until the end of the Gupta Empire around 475 CE. Toynbee regarded later Indian civilisation as being sufficiently different from the Indic to constitute a different civilisation which he termed Hindu, and which survives today. There is therefore a limited memetic continuity between the modern Indian meme pool and Sumeric ancestors. The modern Western meme pool developed in Europe in the Dark Ages, but is an offshoot of the Hellenic civilisation which included the Roman Empire and began in Greece and the Aegean around 1300 BCE. The predecessor of the

Hellenic civilisation was the Minoan which originated in Crete around 2000 BCE. The Minoan meme pool is thus the ultimate ancestor of our own.

Speciation and extinction, since they are often definite historical events, are easier to identify than directional evolution under selection. Perhaps the high rate of technological development in Western society since the mid-18th century can be seen as such a directional evolution, where the selective pressure is the economic and political power associated with new technology (Hull [20]). Another example may be the progressive elaboration of an immensely complicated calendar by the Mayan civilisation where the selective pressure was the social power and status associated with accurate ability to predict eclipses and other astronomical events. Notice that the selective pressure posited in these cases is associated with power of one sort or another accruing in the hands of elites (priests, scientists) who are capable of generating novel memes or combinations of memes. This is perhaps the easiest answer but not necessarily the only one. Alternatives are suggested by Benzion [3], and in the work of the 19th century American philosopher, Charles Sanders Peirce, who will be dealt with at greater length below.

Toynbee's system suggests that there may be reasonable grounds for placing meme pools at the species level in the gene-meme analogy. Of course one may have some doubts about his interpretation of various details, and many would dispute his diffusionist tendencies (see above), but the general picture he paints, of lines of descent, extinctions and speciations, is highly compatible with a view that treats meme pools as equivalent to species. However, as briefly mentioned previously, meme pools are rarely totally isolated. Toynbee may see the Minoan meme pool as the ultimate ancestor of the Western, but it is arguable that Middle Eastern memes constitute a strong component of the Western meme pool through the influence of Judaism on Christianity. There could be no biological equivalent of this extensive meme flow from one species-level entity to another (except in a bacterial system with extensive horizontal transmission (Speel [42])).

Pursuing this line of analogy just a little further, we might also speculate that, just as small gene pools are more likely to disappear than large ones, small societies are often the most vulnerable to memetic extinction. What is the necessary size of the meme pool to maintain cultural viability? The Tikopia, for instance, subjects of a classic anthropological study by Raymond Firth in the 1920s (Leach [24] p. 27), were a population of about 1300 individuals on a Pacific island of some three square miles in size. This population had been there for some thousands of years, a meme pool in total isolation but nevertheless viable. Only contact with European missionaries finally destroyed it. However, much smaller meme pools like those of the Pitcairn mutineers or the Californian Yahi isolate (Diamond [13], [14]), numbering only some dozens of founding individuals, are frequently subject to a form of cultural decay rather analogous to genetic load (Muller [28]), which might be termed 'memetic load'.

Benzion [3] presents an interesting scheme for the evolution of civilisations through four 'cognitive ranks' of paradigmatic sophistication, namely 1 - preliterate, 2 - literate but non-numerate, 3 - numerate/algorithimical/scientific, and finally 4 - computational/data manipulative. Each of these is postulated to increase its memetic complexity in a sigmoidal manner, before a transition to the next rank. This analysis suggests many interesting lines of research, for instance

in how cognitive rank transition may correspond to paradigm shift in science(Kuhn [22]) or to sociological phenomena.

In summary, memetics suggests many new possibilities for the analysis of civilisations. The state of modern Western civilisation, and how it has changed over time, are primary concerns for modern Continental philosophers. Therefore a discussion of how memetics relates to Continental philosophy is relevant at this point.

5 Memetics and 20th Century Philosophy

Popper's hierarchical concept of World 3 leads to the postulation above of the fundamental propositions of logic as memetic nucleotides. It is important to note that we are not here concerned with what may or may not be true about ancient or modern systems of logic. Logic is learned and therefore subject to the same selective pressures as all other memes.

The basic propositions of logic were very much the concern of Anglo-American philosophers at the turn of the century. Bertrand Russell (1872-1970) and Alfred North Whitehead (1861-1947), having produced their magnum opus on the logical foundations of mathematics, *Principia Mathematica*, were concerned to extend this solid foundation to all language. This endeavour, Logical Atomism, was designed to provide an ideal language which would be the foundation of all sciences. Their failure to do so resulted in Whitehead's rapid movement into mysticism, while Russell turned to other activities such as history and political campaigning.

Despite the despondency of the Cambridge philosophers, the torch of Logical Atomism was taken up by a young Austrian, Ludwig Wittgenstein. In his main early work, *Tractatus Logico-Philosophicus* [50], Wittgenstein describes a logical world built from '*atomic facts*', the constituents of simple propositions, which are either true or false. '*The World*' is the totality of true propositions. There are also pseudo-propositions which arise owing to the illogical structure of human language. For memeticists, the '*truth-value*' of a proposition is of less importance than its ability to replicate; both genuine propositions and pseudo-propositions can be considered as memes.

At this point, it should be pointed out that caution must be exercised in co-opting Wittgenstein and the Logical Atomists as forerunners of memetics. Wittgenstein's world of propositions is static and he has little if anything to say about change, let alone evolution, whereas memes are to be regarded as the component parts of an evolving meme pool, much of which, it must be remembered, may be pseudo-propositional. Wittgenstein ([50], Section 6) regards logic, the a priori part of science, mathematics, ethics and philosophy as pseudo-propositional. Interestingly, an early draft of the *Tractatus* includes the phrase 'a theme in music is a proposition' (*Prototractatus* 3.16021 quoted by Kenny [21]), but the final draft omits this phrase, confining itself to consideration of what is or is not the case, and excluding the vagaries of the symbolic, ethical or artistic as things which, as Wittgenstein insisted, cannot be said, only shown. Nevertheless, a memeticist may retort that what can be shown can be transmitted, and therefore can evolve. One philosopher who was very much concerned with evolution of the symbolic was the founder of what became the discipline of Semiotics, Charles Sanders Peirce (1839-1914).

5.1 Memes and Pragmatism

Peirce [30] was one of the first to reject Hegelian dialectic and assert that consciousness evolves in a Darwinian manner, regarding mental variations as random and negative selection as removing those that are non-functional (tychastic evolution, in his terminology). Peirce's view of thought as consisting of a complex array of atomistic signs and symbols, comes close to the meme concept. His following description of the evolution of symbols bears many similarities to Dawkins' idea of mutating and recombining memes:

'Symbols grow. They come into being by development out of other signs.....we think only in signs...it is only out of symbols that a new symbol can grow... a symbol, once in being, spreads among the symbols. Such words as force, wealth, law, marriage, bear for us different meanings from those they bore for our barbarous ancestors' (Peirce [31]).

Peirce's symbols do not have to be linguistic - his theory leaves room for music and other cultural manifestations. The modern discipline of semiology is a development of Peirce's thought. Aside from Peircian semiology's historical interest as a precursor of the meme concept, his theory of the nature of truth, known as Pragmatism, offers a model for the way that memes can evolve. His world of signs has more flexibility, if less order, than that of early Wittgenstein's Logical Atomism. The basic description of a meme, or sign, does not contain any truth function, that is a meme may be an undeniable fact or a highly absurd piece of nonsense or what Wittgenstein [50] would have termed a pseudo-proposition. There is nothing to indicate how 'true' a meme may be until it is tested in the world. The Pragmatic approach to 'truth' by trial and error offers a potential cultural equivalent of Darwinian evolution in genetics.

5.2 Popper and Evolutionary Epistemology

Before leaving Anglo-American philosophy, Popper must be mentioned again. His concept of World 3 and its similarity to the meme pool have already been discussed. This is one of the strands of thought that leads to the philosophical school known as Evolutionary Epistemology which developed in parallel to the decline of Logical Atomism. In the inter-war era, even Wittgenstein abandoned philosophy for some years and his immediate followers in the Vienna Circle were broken up by the Nazi invasion of Austria. Wittgenstein's later work emphasised the context dependence of language in the form of 'language games'. In *Philosophical Investigations* (Wittgenstein [51]), he ruminates on how an analysis of language treated independently of the language game or 'form of life' in which it is used is essentially meaningless. This led to the post-war school known as Linguistic Philosophy led initially by J.L. Austin (1911-1960) [1]. Opposition to this tendency was provided by Popper, although Moritz Schlick (1882-1936) of the Vienna Circle seems to be prefiguring Popper's concept of World 3 in his *Allgemeine Erkenntnislehre* [31].

The term '*Evolutionary Epistemology*' was coined by D.T. Campbell [5] in a commentary on Popper's work, and has been reviewed recently by Henry Plotkin [33]. A crucial paper is by Leda Cosmides [8], the title of which, 'Has natural selection shaped the way humans reason?' neatly sums up the whole approach, echoing Peirce but in a neo-Darwinian format. Evolutionary Epistemology has become the major trend in epistemology within the Anglo-American world,

thus placing the Darwinian analysis of thought at the very centre of that tradition. In order to begin to reconcile Anglo-American epistemology with Continental post-structuralist thought, it is necessary to examine the Darwinian roots of Structuralism.

5.3 Saussure and Signifiers

The founder of 20th century Continental philosophy was a Swiss linguist named Ferdinand de Saussure (1857-1913). Virtually unknown in his lifetime, his posthumous influence was immense, due to the publication in 1916 of notes taken at his lectures by two pupils. Many of his concerns were the same as those of the Anglo-American philosophers of his day: the nature of language, meaning and its correspondence with reality etc., but his results were very different from those of his contemporaries Whitehead and Russell. Saussure was originally a comparative linguist working on the evolution of the Indo-European languages, but his later theories tended to emphasise the 'synchronic' i.e., the existing structure of language at a given point in time, over the 'diachronic', i.e. the evolution of language over the course of time. Nevertheless, much of his terminology is still compatible with the memetic approach.

Saussure's theory revolves around the notions of the '*signifier*' and the '*signified*'. To use an example provided by Sarup ([37] p. 3), in the case of an apple, the signifier is the sound image made by the word '*apple*', but it is the concept of an apple which is the signified (not, as one might imagine, the apple itself). The '*sign*' in Saussure's terminology is the relationship between the signifier and the signified, and it is arbitrary, depending on convention. A case has already been made for equating the propositions and pseudo-propositions of Logical Atomism with memes, but in this case the correspondence is not so easy to tease out. Is the signified the meme? Or the signifier? Or the sign?

A further difficulty is provided by the fact that Saussure's followers, the Structuralists, like the Logical Atomists, were not particularly interested in change. Structuralism emphasises the study of structural relations existing at one moment in time, ie. the '*synchronic*', over the way that these relations change through time, ie. the '*diachronic*', and thus relegates evolution to a position of lesser importance. As Structuralism has turned into Post-Structuralism, there has been a tendency to concentrate on the signifier rather than the signified, which has been interpreted as an attempt to remove the one-to-one correspondence between propositions and reality. This presents a considerable philosophical challenge (especially for Anglo-Americans), but in effect it brings Structuralism closer to memetics. The potential ambiguity present in Saussure's complex triadic system of signifier, signified and sign is removed. For the Post-Structuralists, the signifier is now the dominant unit and can be considered as analogous to the meme. We thus have 'the play of the signifiers' (*le jeu des signifiers*) much beloved of the school of Post-Structuralism known as the Deconstructionists. The process of breaking a text down into its component signifiers is a similarly reductionist process to memetics. Memeticists analysing a complex belief system are concerned with identifying, dissecting and describing the memes that are present in it, in terms of their replicative powers, adaptiveness, selfishness etc.

The leading Deconstructionist Jacques Derrida has presented the notion that we are made out of language. This seems a strange idea to many scientists and Anglo-American philosophers. However, Daniel Dennett [10] has used the meme concept to say something very similar about

consciousness. Dennett sees memes as a kind of software for the *'virtual machine'* of consciousness which runs on the *'hardware of the brain'*. To say that we (or our consciousnesses) are *'made of'* language, following Derrida, is not too far from Dennett's view that our consciousnesses are *'made'* from the complex interaction of memes.

As mentioned above, the deconstructive process which Derrida and his followers apply to texts is the sort of process that memeticists have to apply to culture in general, in order to reduce it to its basic components, the memes or memetic nucleotides. One example of the lengths to which Deconstruction will go to dissect a text is provided by Derrida [12] who devotes a 139 page book to an examination of the word *'Geist'* in the work of Heidegger. Whereas with the Deconstructionists the process is designed to *'shatter'* meaning (Sarup [37]), in memetics the process is intended to dissect the way that culture has evolved. Deconstruction sees itself as a process of reading texts in a radical new way, different to the traditional way of seeing things. So too is memetics a new approach to culture and science and indeed all human learned behaviour and belief - not merely just a revival of cultural evolutionism but a more truly Darwinian reductionist approach to culture.

5.4 Foucault and the Episteme

Just as Deconstructionism and detailed memetic analysis display parallels at the lower levels of the memetic hierarchy, similarities can also be seen between the *'macromemetic'* approach of cultural evolutionism and the theory of succeeding *'epistemes'*, or total systems of thought, described in the famous structuralist work of the 1960s, *Les Mots et les Choses* [16], by Michel Foucault (1926-1984). Foucault advances an argument for a saltatory view of cultural change, with epistemes replacing each other in periods of revolutionary cultural change. The early cultural evolutionists considered above were gradualists in the spirit of early Darwinism. Now that it is apparent that punctuated equilibria may be a feature of biological evolution (Stanley [44]), macromemetics may also admit revolutionary changes. As Madan Sarup points out [37], there are many similarities between Foucault's notion of the *'normative society'* and Thomas Kuhn's independently developed concept of normal science interrupted by periods of scientific revolution [22]. Kuhn's *'paradigms'* are similar to Foucault's epistemes, except that they apply more narrowly to science rather than to culture as a whole.

One of Foucault's principal concerns was to reject any possibility of a single unifying theory. He thus rejects Marxism. It might be objected that he would have done the same to memetics. However, in defence of our nascent discipline, it must be emphasised that memetics is not really a totalising metanarrative. It is not really a *'grand recit'*, like Marxism, where the world is evolving towards a certain inevitable endpoint, for instance in Marxism the endpoint is the achievement of world Communism. Darwinian evolution has no *'guiding hand'* behind it. It may have direction, but that is only in response to consistent selection pressure (Gould [18]). If the selection pressure changes, the direction trend of the response may be diverted or go into reverse. The occasional structuralist accusation that evolution is a *'grand recit'*/metanarrative is therefore unjustified.

6. Conclusion: The Role of Memetics

Dawkins [9] acknowledges his indebtedness to Popper, and to Cloak [7], for paving the way to the meme concept. Memetics thus has both philosophical and anthropological precedents. On the philosophical side, Popper's World 3 is populated with many elements which might be described as memes. Cloak comes from the anthropological tradition, and much 19th and early 20th century anthropology had a strong evolutionary component. Dawkins' real contribution can be seen as the fusion of cultural evolutionism with a reductionist approach derived from the gene selectionist school of evolutionary biology. Cavalli-Sforza and Feldman's `culturgens' [6] and perhaps even White's `symbolants' [47], were partial anticipations of this approach. Saussure's work on `signifiers' stemmed from his early research in the evolution of languages. 20th century structuralist philosophy thus has its roots in evolutionary theory. The emphasis that Structuralists place on discontinuous change and an opposition to metanarratives, has led some of the proponents of Structuralism to insist that it is incompatible with Darwinian evolution. However, now that it is appreciated that discontinuous changes e.g. saltations, may occasionally appear in biological evolution, the incompatibility no longer applies. One of Anglo-American philosophy's most flourishing branches is Evolutionary Epistemology, which also derives from Popper's Darwinian approach to the themes of consciousness and the history of ideas. Memetics thus represents a possible framework for the reconciliation of the two main branches of Western philosophy.

WHY THE “THOUGHT CONTAGION” METAPHOR IS RETARDING PROGRESS OF MEMETICS

Abstract

The most generally accepted definition of the meme, as a 'unit of information residing in a brain' (Dawkins 1982), implies a meme-host duality which is the basis of many current developments in memetics, in particular the notion that the passage of such memes (or homoderivative mnemons, following Lynch 1998) from mind to mind constitutes a process that may be considered as 'thought contagion'. A critique of religious belief and other non-rational systems of thought, as 'mind viruses' (Dawkins 1993), has been built upon such a meme-host duality. This paper provides two objections to the 'thought contagion'/'mind virus' theory: a) that the concept of a transmitted belief, as opposed to transmitted information, is highly problematic, and b) that in any case the concept of a meme-host duality is equally suspect. It is suggested that the least philosophically problematic constitution for a science of memetics would be to adopt a behaviourist stance towards memes, to restrict the use of the term to those replicating cultural phenomena which can be directly observed or measured (Benzon 1996). This would release us from the difficulties of the indefinable meme-host relationship, and also have the merit of making memetics more directly comparable to animal behavioural ecology, to the existing branch of social psychology known as social contagion theory, and to the sociological field of empirical diffusion studies.

Key words: meme, belief, religion, linguistic behaviourism, mind virus, thought contagion, social contagion, diffusion of innovations.

1 Introduction and Summary

This article is designed to complement the on-going debate concerning the definition of the term 'meme', by investigating some of the limitations consequent on certain usages of the word. Broadly, my intention is to show that what is probably the most popular, even one might say the 'orthodox', definition of the meme as a 'unit of information residing in a brain' (which I shall term Dawkins B, see Dawkins 1982), presents us with serious philosophical difficulties that may hamper (and indeed are already hampering) the development of memetics as a science. I shall argue that an earlier and broader picture of the meme as a 'unit of cultural transmission, or a unit of imitation' (which I shall call Dawkins A, see Dawkins 1976), is in many respects a better working definition, despite the fact that it is now generally regarded as obsolete. The conclusion of this argument is that the best current definition is that of Benzon (1996) although, as with any definition, there is scope for refinement.

I shall focus on two main theses, which develop as a consequence of discussing the difficulties that lurk within Dawkins B:

1. There can be no population memetics.
2. Memetics cannot be used to study why beliefs spread.

In brief, thesis 1 is consequent on the impossibility of quantifying meme frequencies in populations, since this requires a clear meme-host relationship and that is precisely what we cannot obtain in most cases, as will be shown. Thesis 2 is consequent on the impossibility of accurately identifying when belief has been replicated or transmitted. It is possible to accept thesis 2 while still rejecting thesis 1. However, if thesis 1 is accepted, thesis 2 is a necessary consequence.

Some may be horrified at thesis 1. Part of the initial appeal of memetics was that it seemed to suggest that the powerful theoretical tools of population genetics might be applied to revitalise the venerable but rather moribund field of cultural evolution. The present author has also subscribed to that view (Gatherer 1997a, b, c, 1998) so this article is partly a self-criticism. If we can have no *population* memetics, some might feel that there is no point in having *any* memetics. However, memetics may still be scientifically applied in other ways, and may still make a contribution to the humanities. In particular, I shall attempt to argue that memetics may be best constituted as a science by adopting a behaviourist perspective. By behaviourist, I do not mean the rigid 'neo-behaviourist' tradition of Skinner (eg. Skinner 1972), but in the broader sense of Watson (see Cohen 1979). Under the terms of such a 'soft' behaviourism, only observable behaviours and artefacts would be considered, and memetics would cease to concern itself with unobservable mental entities such as beliefs or thoughts. Benzion (1996) has previously come to this conclusion, but by a different route. This critique is particularly directed against those who see memetics as a science of 'thought contagion' (eg. Lynch 1996a), presumably extrapolating from the well-established branch of social psychology known as social contagion theory. This latter dates back to LeBon's 'Psychologie des foules' in 1895, and Baldwin's study, in 1897, of what later became known as the 'Werther Effect' (apparently contagious suicidal behaviour, see Phillips 1974; reviews of social contagion by Hamilton and Hamilton 1981, Levy and Nail 1993). Importantly though, social psychology is largely (although admittedly not exclusively) constituted as a behaviourist and empirical science, and thus avoids many of the philosophical difficulties that 'thought contagion' theory finds itself in.

The first step is to examine why: a) we cannot have a meme-host duality, and why therefore: b) we cannot quantify meme frequencies per capita, and why we therefore: c) cannot have any population memetics.

2 Thesis 1: Memes - To Have and Have Not

2.1 Dawkins A and Dawkins B

I shall refer to Dawkins' original formulation of the meme as Dawkins A (Dawkins 1976). Several years later, Dawkins presented a revised version of the meme which I shall refer to as

Dawkins B (Dawkins 1982). According to Dawkins (1982), the revised version was intended to clarify the relationship between memes and cultural products. Here it will be argued that the Dawkins B definition did not clarify the situation but trapped memetics in a conceptual impasse from which it has not yet emerged.

For reference, the original formulations are as follows:

Dawkins A: *'...a unit of cultural transmission, or a unit of imitation.'* (Dawkins 1976, p.206); *'Examples of memes are tunes, ideas, catch-phrases, clothes fashions, ways of making pots or of building arches'* (Dawkins 1976, p.206); *'Popular songs and stiletto heels are examples. Others, such as the Jewish religious laws...'* (Dawkins 1976, p.209); *'Perhaps we could regard an organised church, with its architecture, rituals, laws, music, art and written tradition, as a co-adapted stable set of mutually-assisting memes.'* (Dawkins 1976, p.212); *'Memes for blind faith have their own ruthless ways of propagating themselves.'* (Dawkins 1976, p.213).

Dawkins B: (referring to the original Dawkins A definition, above) *'...I was insufficiently clear about the distinction between the meme itself, as replicator, on the one hand, and its 'phenotypic effects' or 'meme products' on the other. A meme should be regarded as a unit of information residing in a brain..... It has a definite structure, realized in whatever physical medium the brain uses for storing information....I would want to regard it as physically residing in the brain.'* (Dawkins 1982, p.109); *'The phenotypic effects of a meme may be in the form of words, music, visual images, styles of clothes, facial or hand gestures.....'* (Dawkins 1982, p.109).

The central flaw in the 'thought contagion' and mind virus' hypotheses may be summed up in a single phrase: these theories require individuals to *have* memes. In Dawkins B, the state of having a meme is taken as synonymous with the state of having a certain informational pattern in the brain. But, as will be demonstrated, this is a poor basis for building any theory of cultural evolution. Others have criticised memetics by claiming variously that the meme is a useless abstraction, or that memetics has nothing to contribute to the theory of cultural evolution, or that culture does not evolve (eg. Rose et al. 1984, Barbrook 1996, Gould 1996, Harms 1996, Pinker 1998). I do not support such criticisms, which call the validity of memetics into question. My criticisms, by contrast, are intended to strengthen the theoretical basis of the memetics movement. If we are to have a cultural evolutionary theory, then we need units of replication/selection, and the meme concept would seem to be as good a way as any of approaching this problem. The mistake lies in the frequent assumption that individuals *have* memes. But because, as will be shown, we cannot assign memes *to* individuals with sufficient reliability or regularity, we cannot produce meme frequencies, defined as the proportion of individuals in a population that possess or have a meme. Gene frequencies *are* absolutely necessary to population genetics, and if there is to be a population memetics we correspondingly need to have unambiguous meme frequencies. There are some circumstances in which we can derive a statistic of this sort but, as will be demonstrated, this kind of 'meme frequency' statistic, if we are to have it at all, must be defined in a purely behaviourist manner.

By contrast, individuals do *have* genes. They may or may not pass them on to the next generation of individuals. However, whatever the reproductive success or otherwise of an individual, that individual carries those genes around in its body for the duration of its life. A population

geneticist may derive allele frequencies as the proportion of individuals who carry one gene sequence or another. Gene frequencies are of course abstractions, pure quantitative values, but they are abstractions which relate directly to a physical reality, ie. the reality of gene sequences within the bodies of individuals. Thus, providing the required technical methods are available, one may derive an unambiguous estimation of gene frequencies which are comparable between one population and another.

Memes, on the other hand, are more difficult to pin down. Dawkins A included concepts, cultural artefacts and subjective states such as beliefs, whereas Dawkins B restricted memes to units of neural information giving rise to behaviours or the production of artefacts (Dawkins 1982, p.109). Dawkins is careful to stipulate that when a meme is transmitted from one brain to another, it is not necessary that exact neural configurations are reproduced. Two individuals who are exhibiting the same mental state, entertaining the same idea, performing the same behaviour, are taken to have the same meme, for all intents and purposes - even if their neural configurations are not identical. Thus at this most basic physical level, Dawkins B memes are less tangible than genes. They are merely informational specifications within brains.

2.2 Memes in Action

Let us take an example to see how such a Dawkins B framework would apply to a simple system. There is a method of tying a necktie which is called the Windsor knot (named after King Edward VIII). Windsor knots provide a better knot volume and more elegant shape than the standard method of tying a necktie. There is even a mutant form, the half-Windsor, which is slightly simpler and which many people tie in preference to the full Windsor. If we first apply Dawkins A, the knot itself is a cultural replicator, and therefore a meme, as is *also* the idea of tying the knot. *Both* the Windsor knots themselves and the neural activity involved in tying them are taken to be capable of spreading through populations (for instance, the Windsor knot has made a distinct comeback now that ties are a little wider again). By contrast, Dawkins B would restrict the meme to the neural correlates of knot-tying activity, with the knot itself simply becoming the cultural artefact, or 'meme product' (Dawkins 1982, p.109) consequent on the activity of the meme in the mind/brain of the tie-wearer.

To reiterate, in Dawkins B, two people who know how to tie a Windsor knot have the same meme, even if their neural configurations producing this activity are widely different. Likewise, when a Windsor knot is taught, the pupil need not have the same neural configuration as the teacher. The important thing is that both individuals can think of the Windsor knot, and can tie it correctly. Under these circumstances, it is said that meme transmission or replication has occurred.

2.3 Two Difficulties

2.3.1 Difficulty no.1 - How do we observe a (Dawkins B) meme?

Two difficulties arise as a consequence of this Dawkins B definition. The first of these is the less serious and is acknowledged by Dawkins (1982), although he gives little indication that he thinks it *is* a difficulty. This difficulty is that the flexibility that he allows in neural configuration

corresponding to a Dawkins B meme, the fact that it is *just* a unit of information, presents us with no means of identifying memes separate from their manifestation in the outside world, i.e., separate from their 'meme products'.

Even if one were able to use some method of scanning an individual's brain to discover the internal neural configuration, we would not be able to identify the Dawkins B memes of that individual. As far as neurobiology is currently concerned, Dawkins B memes must be abstractions. This is not a problem as far as mathematical modelling is concerned, nor is it a problem for systems theory-oriented memeticists (eg. de Winter 1984). However, for those with a more empirical bent, those who would like to study memes 'in the wild', it is evident that memes, *even under the rules of Dawkins B*, are only defined *by their manifestations*. Those of us who wish to do empirical memetics are thus left in the position of looking at 'meme products', which *are* admissible as actual memes under the more flexible rules of Dawkins A. Little therefore seems to be achieved by the 'refinement' of Dawkins A to Dawkins B, other than to require that we continually remind ourselves that the cultural artefacts we are studying are not the 'real' memes but that these 'real memes' are unobservable informational entities in some brains somewhere.

This first difficulty, although inconvenient, is not fatal. It produces a certain philosophical awkwardness, but the general schema of Dawkins B would still be functional if we were able to assign the abstract memes unambiguously to individuals, and thus derive meme frequencies per capita of human population. But this is something we *cannot* do, for the following reasons.

2.3.2 Difficulty no.2 - How do we quantify a (Dawkins B) meme frequency in an observed population?

This second difficulty is considerably more serious, since it disqualifies both the population memetics and 'thought contagion' models of cultural change. Both of these *depend* on a meme/carrier-of-meme or meme/host relationship, a necessary consequence of Dawkins B. In the population memetics approach, the meme is regarded as coding for a meme product which may or may not contribute to the fitness of the individual that carries it. In the thought contagion model, the relationship is considered as more that of virus/host. This is more than just a nicety of semantics, since the decision to adopt one or the other basic perspective can lead to different abstract mathematisations of memetics. For instance, compare Cavalli-Sforza and Feldman (1981) for a population memetics approach where memes (or 'cultural traits' as they term them) are primarily transmitted 'vertically' within families in a manner precisely analogous to the vertical transmission of genes and an iterative generational model is used with an emphasis on fitness and selective advantage; versus Laland (1992), Lynch (1998) and Takahasi (1998) for contagion approaches which emphasise 'horizontal transmission' and the reproductive, rather than selective, efficacy of the meme. Cavalli-Sforza and Feldman (1981) also present models of the contagion variety, where transmission of the 'cultural trait' is horizontal between siblings and unrelated individuals, and the mathematics uses equations from epidemiology rather than population genetics. As Wilkins (1998) points out, both the epidemiological and population genetics methods are derived from the same basic mathematical models of differential reproduction, but the emphases in each case are different.

However, whatever the relative merits of the mathematical systems, in neither case is it possible *in practice* to accurately derive any quantification of meme-host relationships. The example of the Windsor knot will again serve as an illustration. Let us imagine a room of 100 individuals, only one of whom can tie the Windsor knot, and that individual is the only one wearing the Windsor-knotted tie. If we consider the frequency of the Windsor knot meme to be the frequency of the actual occurrence of the knot (taking a Dawkins A-type interpretation), then we have a frequency of $p=0.01$. If, on the other hand, we take a more orthodox Dawkins B interpretation, and consider the frequency of the Windsor knot meme to be the frequency of the neurally encoded ability to tie the knot, i.e., the mental informational unit corresponding to the knot, then again we have a frequency of $p=0.01$. The two approaches would seem initially to be in agreement.

This situation becomes rapidly more ambiguous when our tie-wearing individual proceeds to tie the knot around the necks of all the other individuals in the room. The frequency of our meme as defined by the occurrence of the knot (Dawkins A) becomes $p=1$. However, the frequency of the neurally encoded ability (Dawkins B) remains $p=0.01$ (unless we allow that some of the individuals learned how to tie the knot while the process was being performed on them, in which case it will increase).

This thought experiment demonstrates that Dawkins A has the advantage of telling us about the change in frequency of a cultural artefact. However, it tells us nothing about any neural events underlying that. We have a change in Dawkins A meme frequency from $p=0.01$ to $p=1$, but that does not reveal the fact that our knot-tying individual is the only one with the knowledge of how to tie the knot. Conversely, under a Dawkins B interpretation, we have no change in meme frequency, but a radical change in the cultural situation of our population. Thus our choice of meme definition places us in two very different situations regarding analysis of the above thought experiment. Furthermore, under the Dawkins B schema we cannot *in any case* identify memes objectively, but only *infer* them from their 'meme products'. If we do not see the single individual tying all the knots, we might incorrectly infer that the other 99 individuals in the room have acquired the Dawkins B meme for knot-tying, and mistakenly place our Dawkins B meme frequency value at $p=1$. Again, if one of the other individuals in the room secretly knows how to tie the Windsor knot but is not disposed to divulge this fact, then we actually have a Dawkins B meme frequency of $p=0.02$, but we cannot ever know this empirically. Only a selective event (eg. a million dollar prize for Windsor knot tying ability) might suddenly reveal the real Dawkins B meme frequency.

2.4 Dawkins A is Better than Dawkins B

To recap, Dawkins A provides us with information about the *cultural state* of our group of 100 individuals, but tells us nothing about what is going on inside their heads. Dawkins B tells us nothing about the change in cultural state of our group, but rather focuses on *unobservable and merely inferred events* going on inside their heads. Since memetics is a theory of cultural evolution, Dawkins A is preferable as *it allows us to look at culture*. Dawkins B diverts us into conjectures about which memes reside in whose heads, regardless of the objective cultural state of our population. This is the principal reason why there has been little or no empirical memetics in the last 22 years. Dawkins B is not a sound basis for any empirical science, as it relegates the

observable, objective manifestations of culture to a subsidiary status. It takes all the data we can gather and dismisses it as mere 'meme product', and leaves us tangled in endless speculation about unobservable mental units of information.

Dawkins A, by treating the objective bits and pieces of culture as memes, frees us from the requirement to chase unobservable entities. It also frees us from the meme-host relationship, since Dawkins A memes, as artefacts and behaviours, need not have hosts. Indeed artefacts definitely do not have hosts. Of course Dawkins A is a broad definition and *also* classifies unobservable mental entities as memes. But Dawkins B turns the unobservable mental entities into the *main objects of study*.

2.5 Further Difficulties with the Meme-Host Relationship

Recall the thought experiment involving the room of 100 individuals and the Windsor knot. We saw that in order to identify accurately the true number of individuals who can tie the Windsor knot, ie. the frequency of the hosts of the Windsor-knot-tying meme under the rules of Dawkins B, we might have to produce selective conditions which reveal the full extent of ability to tie the knot. However, even if we can do this, we still cannot say that the individuals capable of tying the knot are *permanent* hosts for any Windsor knot Dawkins B meme, in the way that they may be hosts for any particular gene. All that we *see* is knot tying activity, and a resulting change in the frequency of knots. But knot-tying activity alone (and what other evidence do we have that the individual 'has' the Dawkins B meme?) does not give grounds for postulating any permanent meme-host relationship.

Hewlett and Cavalli-Sforza (1986), in their extensive study of cultural traits in the Aka pygmies, adopt just such a technique of asking who can perform a particular skill (50 skills are considered ranging from hunting techniques, fruit gathering, and sexual behaviour, to songs and dancing). They are therefore able to build up a picture of who is able to do what, and from whom they learned it. The result, however, tells us more about social structure and relations than it does about selection pressures or any changes in the cultural state of the society under consideration (except for the observation that the Aka have recently abandoned hunting with bow-and-arrows for hunting with the more lethal crossbow - but note that in this single instance it is no longer ability but an artefact that is under consideration). Notably, many of the skills are possessed by high percentages of the population. For instance 99% of adult males know all net-hunting techniques, 98% know all food gathering techniques, 100% know all sexual techniques. Among adult females, percentages are equally high. The only distinct partition among the adult population is that females are less knowledgeable concerning hunting (only 59% know all hunting techniques) while males are less knowledgeable about food preparation (only 47% of adult males are any good in the kitchen as compared to 100% of adult females). The homogeneity that arises from Hewlett and Cavalli-Sforza's analysis is precisely a consequence of their decision to examine ability to carry out skilled activities, as opposed to a more behaviourist approach of observing and quantifying performance of skills over time. Referring back to the thought experiment above, they are in the same position as one who attempts to quantify knot-tying *ability*.

A later paper from Cavalli-Sforza's school (Guglielmino et al. 1995) adopts a wider perspective and compares the total cultural pools of different populations. This approach does not require the difficult task of assigning Dawkins B memes (or cultural traits) *to* individuals, since a population is deemed to possess a cultural trait if that trait, usually defined as an artefact or behaviour, exists within it somewhere.

As we shall see later, to postulate that anyone who *can* perform a certain cultural activity, *has the meme for* that activity, leads us into even deeper problems where conceptual memes are considered.

Under Dawkins B, there is no easy way to circumvent this problem. Among the unsatisfactory alternatives, one might postulate *another* meme for 'wearing the Windsor knot', independent of the one for tying it. This might enable us to say that the frequency of the Dawkins B 'knot-tying' meme in our room is $p=0.01$, and remains so, but the frequency of the Dawkins B 'knot-wearing' meme goes from $p=0.01$ to $p=1$. But what is the neural process that underlies merely passively wearing the knot? Whereas one might easily concede that performance of a skill involves a specific neural activity, which may be reproduced every time the skill is performed, passive states are less easily coupled to neural processes. A similarly difficult example is the cultural trait for 'acceptance of the Fascist salute' (Cavalli-Sforza and Feldman 1981, p.64). *Tying* the knot, or *giving* the salute, are behaviours which presumably must be underlain by neural activities of some sort, unobservable though they certainly are. But what neural activity underlies simply wearing a certain tie, or accepting a certain salute, or travelling to work by train? One may of course easily quantify numbers of individuals travelling by train, or the number of individuals wearing ties, but these statistics would *not* represent Dawkins B memes. Thus a 'tie-wearing' Dawkins B meme is not a solution to the problem.

2.6 How do we Quantify the Frequency of a Conceptual Meme?

With conceptual memes, the problems become even more difficult. The memetics of concepts, specifically religious concepts, is considered by Dawkins (1993), but the major venture into this territory is by Lynch (1998). Lynch uses the term 'mnemon' to indicate an abstract unit of memory.

'Thus, the principle abstractions manipulated with memetics theory are memory abstractions, or mnemons' (Lynch 1998, Section 4).

This is not dissimilar to the Dawkins B meme, the 'unit of information residing in a brain', although of course one might insist that Lynch's mnemons refer only to the memory aspect of neural architecture. What is clear is that Lynch considers *awareness of* simple statements, or *belief in* simple statements, to be mnemons, and that the transmission or replication of such mnemons is the basis of the process of 'Thought Contagion' (Lynch 1996a).

Thus Lynch makes statements such as the following Lynch 1998, Section 12):

'Take the mnemons expressed by the following 3 statements, for instance:

Mnemon A: "There is only one true God".

Mnemon B: "Christ is Lord".

Mnemon C: "Unbelievers are damned".

Mnemon D: "Earthly life is better among believers".'

[There are of course actually four of them, but I quote verbatim. As I have attempted to demonstrate throughout this article, 'Thought Contagion' theory pays scant regard to the accurate quantification of memes].

These statements, or more exactly *awareness of* these statements, are taken by Lynch to be encoded or somehow instantiated in memory. The reader is referred to his article (Lynch 1998) for further examples involving birth control, church attendance etc. Individual concepts are thus taken as mnemons which exist in the heads of their hosts.

Let us accept this system at face value for the moment, and consider such a concept-mnemon: 'Napoleon died in 1821'. This has been physically replicated in print many times throughout history books. An individual who is aware of this might be said to 'have' this meme/mnemon, under Dawkins B or Lynch. However, this individual is also capable of transmitting a vast variety of other related memes/mnemons, such as 'Napoleon died in 1820', 'Napoleon died in 1819' and so on. Now does this individual *have* these mnemons as well? The fact that the first option is factually correct and the other two are false merely perhaps makes it more likely that the first option will be transmitted (perhaps in the selective context of a history exam). However, any individual who has heard of Napoleon *at all* will be *capable* of constructing and transmitting an infinite variety of mnemons of the form 'Napoleon died in *x*'. If we accept that any individual who is *capable of tying* a Windsor knot *has* the Windsor knot meme (and the Dawkins B interpretation *would* seem to imply this, and so would Hewlett and Cavalli-Sforza 1986), then we must accept that anyone who is *capable of transmitting the concept* 'Napoleon died in 1819', *has* that mnemon: 'awareness of the concept that Napoleon died in 1819'. If we can transmit something, we must be aware of it, unless we are transmitting in an unconscious state.

Similarly, to return to Lynch's example, anyone who has the mnemon A, above: 'There is only one true God', must also have the mnemons: 'There are only two true gods', 'There are no true gods' etc, since that individual would be capable of transmitting these mnemons. Even if that individual does not actually transmit any of the mutant derivatives of the first mnemon, that person would still be *aware of* the alternatives and thus, according to Lynch's rules, must *have* the mnemons for those alternatives. Since the alternatives are in principle infinite (ie. 'there are only *x* true gods', for *x*= 0 to infinity), Lynch's system of conceptual mnemons, taken as *awareness of* any particular statement, inevitably leads us into a picture of the human mind as host to an *infinite* array of potentially transmitted concepts. This is clearly unsatisfactory.

The problem of dealing with conceptual mnemons/memes as stored statements, or stored awareness of statements, is a further strong stimulus to abandon the strained host-meme correspondence. We have to consider memes as cultural entities which do not *belong to*, or parasitise, any individual. For this reason, Dawkins A is again a preferable definition. Individuals may be involved in the *production* of memes, but those memes/mnemons are *not* resting latent in

the individual as a gene does. This position will be developed further once we have considered thesis 2.

In summary, since memes (defined by Dawkins B) are not directly observable, we can only study their meme products. Furthermore we cannot assign Dawkins B memes to individuals with any reliability since the relationship of a meme product, whether behaviour, artefact, or concept, to the hypothesised unobservable Dawkins B meme that produces it, is always a difficult one. Consequently, we cannot derive meme frequencies per unit of human population with any reliability. Without such reliability, there can be no population memetics.

3 Thesis 2: Lies, Damned Lies and Memetic Transmission

3.1 Beliefs Concerning a Simple Statement

Thesis 2 is that memetics cannot be used to study why beliefs spread. Note that the phrase 'How Belief Spreads Through Society' is the subtitle of the book on memetics by Lynch (1996a). One possible difference that might be posited between the mnemonic 'Napoleon died in 1821' (N1821) and other mnemons of the type 'Napoleon died in x', is that N1821 *is believed* and the others are not. Perhaps I *have* the meme N1821 *because I believe it*. The study of belief states has fascinated, perhaps obsessed, memeticists ever since Dawkins, and indeed memetics is best known to the general public for the aggressive critique it has provided of religious belief as a 'mind virus' (Dawkins 1993).

However, there are also serious problems with the attribution of memetic status to belief states. Lynch (1998) holds beliefs in statements to be mnemons *in their own right*. We therefore have 'awareness of the statement that abortion is a mortal sin' as *one* mnemonic and 'belief that abortion is a mortal sin' as a *different* mnemonic. Similarly (Lynch 1998, Section 9):

*'Mnemonic P is the belief that "bee pollen invigorates".
Mnemonic Q is awareness of the "bee pollen invigorates" proposition.'*

Bearing this in mind, let us further analyse the example of the statement 'Napoleon died in 1820' (N1820). If a teacher deliberately transmits this false statement to a pupil and the pupil believes it, then we cannot say that *belief* has been replicated or transmitted, since the teacher does not believe in this statement. According to Lynch's system, the mnemonic 'awareness of N1820' *has* been replicated, but the mnemonic 'belief in N1820' has not. The same applies to misunderstandings, where the teacher attempts to transmit the correct statement (N1821) but the student ends up believing an incorrect version. Transmission of belief is clearly far more problematic than transmission of information. Where transfer of information alone is concerned and belief is disregarded, the misunderstanding is merely a mutational event, an error of information flow. Likewise, deliberate lying would still be an accurate transmission of information, regardless of the credence given to that information. Despite these difficulties in the transmission of belief, memeticists frequently give the impression that transmission of belief is a straightforward matter of the replication of one person's belief in the mind of another (eg. Dawkins 1993, Lynch 1996a).

No matter how often a teacher repeats a statement, there can be no guarantee that the pupil will believe the statement. Many factors may influence the outcome, but that outcome is not a matter of simple replication of the teacher's beliefs in the mind of the pupil. Belief is not transmissible, but is something that happens *after* the transmission of information. While we *can* often observe the communication of information, we can *never* directly observe transmission of belief.

Information and belief are not the same kind of thing. Lynch's system, that has 'awareness of x' and 'belief in x' as two variant forms of *the same kind of thing*, ie. as mnemons, is based on a highly doubtful ontology.

3.2 Belief at the Dawn of Memetics

Lynch's conflation of information with belief was not the first incidence of this error in memetics. One of the examples that Dawkins (1976) gives of a meme is 'belief in life after death', although he actually quotes this from a personal communication by Humphrey (Dawkins 1976, p.206-207). When a meme 'parasitises a brain' (quoting Humphrey again - and here we have one of the earliest uses of the meme-host perspective), it is the transmission of belief that is taken to matter. Religious leaders acquire disciples, then larger sets of followers and eventually a whole church by transmitting the necessary set of memes for their particular religion, secured by other memes such as 'faith' and 'fear of divine retribution' which are co-adapted to ensure that the other memes are not easily cleansed from their hosts. This is the standard memetic view of religion, initiated by Dawkins (1976) and developed further by Dawkins 1993 and Lynch 1996a. What is under consideration in these analyses is the spread of belief.

Or is it? Dawkins' original discussion soon veers away from belief and into more abstract territory, referring to the 'idea of God' Dawkins 1976, p.207). This is not the same thing as belief, in fact is rather akin to the idea of a flat earth, but Dawkins fails to point out the distinction. Like Lynch, Dawkins appears to see awareness of the concept of God, and belief in the actual existence of God, as similar kinds of thing, just two memes - different memes admittedly, but nevertheless the fact that one is a concept and the other a belief is not seen as a serious problem. Later, in discussing scientific theories, he slides from memes-as-beliefs to meme-as-ideas with a disconcerting rapidity. For instance, we soon have: '...all biologists [who]...believe in Darwin's theory', equated with: '...every individual who understands the theory....' (Dawkins 1976, p.210). The absurdity of this is illustrated by the fact that I understand everything about fundamentalist Christian theology; raptures, pre-millenarianism, dispensationalism, total depravity, predestination and irresistible grace (yes, I am Scottish, in case you were wondering). However I don't believe a single word of it. By contrast, when it comes to Darwinism, I both understand and believe.

To recap on thesis 2, that memetics cannot be used to study how beliefs spread: an individual may have a set of beliefs, but these cannot be memes, since a) they cannot be transmitted. All that can be transmitted is information. Belief is not itself information, but an attitude towards information. By having statements and belief in statements as mnemons, Lynch is saying that the attitude towards a mnemon is itself a mnemon. Additionally, b) the only empirical evidence we have of belief is through behaviour, whether linguistic behaviour (eg. uttering 'I believe' - a performative utterance in the jargon of linguistic philosophy), or any other cultural manifestation of belief. One may copy the behaviour, but whether this actually leads to belief is another matter

entirely. Therefore beliefs themselves do not qualify as memes/mnemons in any meaningful sense.

4 Belief Systems as Complexes of Behaviours

Having stated my two theses: 1, that there can be no population memetics using Dawkins B or the mnemon system (Lynch 1998), since there can be no reliable calculation of meme or mnemon frequencies per unit of population, and 2, that memetics cannot be used to study how beliefs spread, since belief is not transmissible but occurs, or fails to occur, independently in the recipient after transmission of information, I shall attempt to put forward an alternative. This is a behaviourist scheme, which treats memes as cultural events, behaviours or artefacts which may be transmitted or copied. Outside the occurrence of the event, the practice of the behaviour, or the lifetime of the artefact, the meme has no existence. The meme does not 'go anywhere' when it is not manifested. It is *not* stored in some neural data bank, some internal meme repository. Lynch (1998, Section 4) would have us believe that the unexpressed meme: 'resides very redundantly in someone's brain', but again this conjures up images of vast memory banks of mnemons encoding 'awareness of statement x', not a view of the architecture of the brain that is very consonant with current thinking in either neurobiology or linguistics. By contrast, the behaviourist meme *is* its own manifestation. This definition is basically Dawkins A, but with the mentalistic component of that meme definition stripped out. It is a similar definition to that of Benzon (1996).

Let us take the example of a laboratory scientist, an evolutionary ecologist, carrying out a complex set of daily behaviours: fruit flies may have to be fed, progeny counted, genomic DNA prepared, agarose gels loaded, data processed on a computer etc. The belief system behind this may be Darwinism, and the particular set of behaviours may be designed to quantify genetic differences in fly genomes from different habitats. None of the behaviours in the laboratory make much sense without the presupposition of belief in Darwinian theories of evolutionary change. The scientists also say certain typical things to each other; they count allele frequencies, they discuss selective pressures, they debate the significance of results for the theory. These are transmitted behaviours; anyone hoping to become a successful evolutionary fly ecologist will have to copy and master them all. They are memes in their own right. Likewise, a priest of a religion may perform a standard set of ritual activities, say standard things in a religious context, live in a certain way and encourage her flock to do likewise (or perhaps to have lots of children). Novice priests have a lot of memes to copy too. These things presuppose the belief system. Religions, political doctrines and scientific theories may be referred to in terms of the behaviour they produce. This is not quite the same thing as saying that they are defined in terms of this behaviour, but where memetic transmission is concerned, much of what is transmitted is behavioural. In both cases, however, there is still room for individuals who perform the behaviours without believing the underlying theory. There are skeptics and jokers, subversives and cynics, in every profession.

Nevertheless, behaviour, and the artefacts produced by behaviour, such as micropipettes, laboratories and cathedrals, *is* more easily quantified than conceptual abstractions. It is possible to measure the increase in the number of Christian churches per capita in the Roman Empire, to measure the number of scientific articles on the subject of Darwinism per total articles published,

to measure the percentage of Aka hunters carrying crossbows, to measure the percentage of votes cast for political parties defining themselves as socialist etc. *These* are our meme frequency statistics, or as near as we shall ever get to such a thing. *These* memes are behaviours, or artefacts that are the products of behaviour, and *not* abstract informational instantiations in individual brains.

And, crucially, individuals do not *have* any of these memes. They build them, say them, do them, make them, assent to them or deny them, but the memes are entirely outside the human beings that generate them. These meme frequency statistics are *not* per capita of human populations, and therefore *do not constitute a body of data which is formally analogous to that of population genetics*. For this reason, there can be no population memetics.

5 Social Contagion Theory and its Relevance to Memetics

In this section I ought to be clear that I am discussing the social contagion school of social psychology, and not the thought contagion wing of the memetics movement. Social contagion psychologists refer to a wide variety of socially transmitted phenomena. These can include everything from major social problems such as aggression (Wheeler and Caggiula 1966), mass hysteria phenomena (Stahl and Lebedun 1974) and antisocial behaviour (Sigelman and Sigelman 1976), right down to such things as contagious laughter (Freedman and Perlick 1979), jaywalking (Lefkowitz et al. 1955), hyperventilation (Moss and McEvedy 1966), binge eating (Crandall 1988) and coughing (Pennebaker 1980). The reader is referred to Levy and Nail (1993) for further details and a panoramic review of the field.

One theme of contagion research is the modification of epidemiological modelling to the particular phenomenon under consideration (Hamilton and Hamilton 1981). In most cases however, the approach is purely empirical and no mathematization is presented. Additionally, social psychologists tend to have little to say about evolution. Social contagion phenomena are either generally seen as unimportant to the evolution of society as a whole or, perhaps more frequently, the social psychologist is raised in a tradition which rejects the entire notion of social evolution. Thus in 'traditional' sociology and social psychological contagion theory, there is little if any reference to selective pressures, competition etc.

Social contagion theorists have tended to split their field into three areas: disinhibitory, echo and hysterical (Levy and Nail 1993). In disinhibitory contagion, what seems to be involved is not the transmission of any meme so much as contagious release of inhibitions which then serves to permit an aspect of the unconscious to manifest itself. The connections with Freudian psychology are obvious (Freud 1959).

Social contagion theory tends to direct itself towards the immediate, spontaneous and transient, such as crazes, manias, and fads. Much of the discourse of pop memetics is concerned with such things. However, if memetics is to explain cultural evolution (and that is surely its aim) then it needs a theory that can deal with more permanent changes in behaviour. Blumer in the late 1930s (cited by Levy and Nail 1993) attempted to enlarge the domain of social contagion theory to include more meaningful social changes such as financial panics, patriotic hysteria, the dancing mania of the Middle Ages and various witch hunts of more recent times. These 'social

epidemics', as Blumer termed them, can result in more serious consequences, since patriotic hysteria can cause genocide or war, financial panics can wreck economies etc.

It should also be remembered that, for the social psychologist, contagion theory is just one of a variety of ways of explaining the behavioural influence of one individual on another in society. To quote Levy and Nail (1993), social psychologists also have to consider:

'...conformity, obedience, persuasion, compliance, deindividuation, social norms, contagion, interdependence, leadership, reactance, social facilitation, social inhibition, social loafing, and vicarious learning...'

as well as the more obvious factors such as education and indoctrination. Memeticists tend to lump all these factors together into transmission or replication (there may be a subtle difference between these last two but in memetics they are often used interchangeably). However, contagion only represents a small proportion of all memetic events. To claim, as Lynch (1996a, b, 1998) does, that an epidemiology-derived modelling system can be applied to the spread of beliefs through society, is very likely to fall foul of social psychologists, who recognise a more subtle taxonomy of human discourse.

Where social contagion theory enters the evolutionary camp, in the work of Cavalli-Sforza and Feldman (1981), the point is made that innovations tend to spread horizontally whereas long-standing elements of culture tend to be transmitted vertically from elder members of families (and are thus analysed using a population memetics approach). Innovation, especially technological innovation, can be an important fact producing major changes in society (eg. the introduction of motor cars, antibiotics, computers etc.), but once established as part of a culture, the horizontal, social contagion model of transmission is frequently superseded by the vertical, population memetics model.

Crucially, however, Cavalli-Sforza and colleagues almost always tend to study the spread of the empirically observable (Cavalli-Sforza et al. 1982, Cavalli-Sforza 1986, Guglielmino et al. 1995, and to a lesser extent Hewlett and Cavalli-Sforza 1986). The distinction between traditional social contagion theory (whether evolutionary or sociological) and 'thought contagion' theory is that in the latter, mental events are under consideration.

Before leaving the subject of social contagion, consider the phenomenon of mass hysteria, a recent subject of much discussion in the Memetics Mailing List. Participants at last year's most publicised funeral were seen on worldwide television to exhibit waves of weeping, shouting and, much commented on, spontaneous and what one might call 'culturally inappropriate' applause. Are we to suppose that the wave of applause represented the passage of mnemons from head to head in a rapid wave of mnemon propagation? And that these mnemons were then immediately translated into the meme product of actual applause? What is happening in a person's head when he hears others applauding and impulsively joins in? What is a 'clapping' mnemon anyway? I know what clapping is, I have done it often enough. I do not belong to a culture in which there is no clapping (*then* it might be conceivable to suggest that I have no clapping mnemon). Since I must 'have' a clapping mnemon, what mnemon do thought contagionists propose is spreading

through a crowd who all already know what clapping is? Is it the 'clap now' mnemonic perhaps? How does the 'clap now' mnemonic differ from the simple 'clapping' mnemonic?

I cannot answer these questions, but if thought contagionists claim that their theory can explain phenomena such as hysterical contagious applause, then they must be able to provide cogent answers to them.

In any case, a more parsimonious approach would surely be simply to adopt a behaviourist stance and just record who is clapping, where, and for how long; no mnemonics, no abstractions of memory instantiation, no homogenic instantiation events, *just behaviour*.

6 Transmission of Innovations

Another related area which has recently been the subject of much discussion in memetic circles, is that of the theory of diffusion of innovations, principally the work of Rogers and his school. Rogers and Shoemaker (1971) trace its origins back to the work of Tarde in 1903, almost contemporaneous with the origins of social contagion theory.

This field however, is mostly about the production of artefacts and/or the adoption of cultural practices, and therefore cannot be easily reconciled with Dawkins B, or the mnemonic approach of Lynch (1998). Typical questions for cultural diffusion studies would be: what is the rate of growth of in the proportion of houses with satellite television and their geographical distribution?, or, what is the growth in the use of catalytic converters and unleaded petrol in motor vehicles?, and so on. Diffusion theory makes no speculation concerning mnemonics or other internal elements in human minds.

For example, in the bibliography of 337 classic diffusion theory-related publications, produced by Brown (undated, probably 1964), only four are reconcilable with a Dawkins B-type memetic approach. Only one of these concerns itself directly with religion: Hawley's study of the uneven acceptance of missionary Catholicism in the southwestern USA (Hawley 1946), although two theoretical papers by Rashevsky deal with beliefs, prejudices (Rashevsky 1951) and ideologies (Rashevsky 1952). The fourth paper is a study of the spread of rumours (Rapaport and Rebhun 1952). The last of these subjects is probably equally compatible with a behaviourist approach, since one may simply record who transmits the rumour (verbal behaviour) and who has already been the recipient of an attempted transmission, without the requirement for any mnemonics of 'having rumour', 'believing rumour' etc. Among the more typical subjects for diffusionists are vaccine use, agricultural practices, medical practices, adoption of fluoridation, spread of cowries as a currency, arithmetical techniques and horse-riding (Brown, undated, probably 1964).

It is significant that neither religion nor belief occur in the index of Rogers and Shoemaker's compendious review of the diffusion research field (Rogers and Shoemaker 1971). These authors list over 1500 articles on diffusion research, but are only able to add one more paper on the diffusion of beliefs, that of Erasmus (1952). Like the social contagion psychologists, diffusionists are overwhelmingly empirical investigators. Their material is the observable and the quantifiable, not the abstract and internal.

7 Who Uses Which Definition?

Dawkins B has almost become the orthodox definition of the meme. The principal point of this paper is that Dawkins B represents a retrograde step from Dawkins A, and that it has been responsible for the spawning of all manner of 'thought contagion' speculation which is an active hindrance to empirical work in the subject, and a source of ridicule in the scientific community at large (as those of us who are academics can verify).

Those cultural evolutionists who do not describe themselves as memeticists nevertheless often use concepts that are similar to those of Dawkins. For instance, Lumsden and Wilson's definition of the 'cultorgen' as: 'the node of semantic memory' (Lumsden and Wilson 1985, p.348) seems to be very close to Lynch's (1998) mnemon, although importantly, unlike Lynch, they do not construct semantic memory as a stack of 'awareness of x' modules. Richerson and Boyd (1978) are less specific concerning their 'culture-types', which is a unit of selection (not necessarily of replication) in a cultural system:

'...natural selection should act on culture-type, increasing the frequency of those items of culturally coded information in a population which.....produce phenotypes that are more successful in passing the culture-type to the next generation' (Richerson and Boyd 1978, p.132)

If, by 'culturally coded information', Richerson and Boyd (1978) imply neural informational units, then this is clearly like Dawkins B. However it is not entirely clear if this is what is implied, since: '...the precise mechanism of inheritance of the code is likely to be largely irrelevant' (Richerson and Boyd 1978, p.132). Whether or not a Dawkins B-type model is implied, Richerson and Boyd do imply a meme-host duality in that they refer to: 'cultural codes as they are transmitted from one individual to another' (Richerson and Boyd 1978, p.132), and their mathematical treatment follows from this.

Cavalli-Sforza and Feldman (1981), as discussed above, tend generally towards a Dawkins A definition in theoretical discussion of their 'cultural traits' (also see Cavalli-Sforza and Feldman 1983, Feldman and Cavalli-Sforza 1984, Feldman et al. 1985), and in practice tend to be more behaviourist, if somewhat irregularly (Cavalli-Sforza et al. 1982, Hewlett and Cavalli-Sforza 1986, Cavalli-Sforza 1986, Guglielmino et al. 1995).

Those who use more orthodox Dawkins B interpretations or close relatives, include de Winter (1984), Dennett (1990, 1991) and Speel (1997), and it is the source for the computer modelling of a simple society, carried out by Doran (1997). Ball (1984) begins with a resolutely Dawkins B interpretation, but then takes it further in claiming that *all* mental contents are memes, including those aspects of information which are products of Skinnerian conditioning. Memes thus constituted are no longer units of imitation but units of mental content. A similar view is expressed by Gabora (1997), who sees memes as the units of mental experience, down to and including sensory qualia such as 'a vivid impression of red'. Preti and Miotto (1997) also define memes as simply 'mental representations'.

Benzon (1996) places memes in the external environment as cultural replicators. Briefly, his central point is that it is artefacts that are copied, and therefore it is artefacts that replicate (albeit

somewhat haphazardly). Like Benzon, I do not deny that psychological traits exist - neither of us is a behaviourist in the sense of Skinner or Ryle - but that they are too intangible to be copied in any meaningful sense of the word. The appeal for a 'soft' behaviourist memetics here, and in Benzon (1996), constitutes a restriction of the Dawkins A definition to the artefactual, and the elimination of those aspects of Dawkins A which are mentalistic.

Thus reconstituted, human memetics might have more in common with the thriving animal behaviourist wing of the subject. For instance Ficken and Popp (1995), when measuring the evolution of the 'gargle vocalisation' of the black-capped chickadee, produce statistics of how many songs of certain types have been produced in a certain period. There is no attempt to assign song memes to individual birds, since individuals have a large repertoire of songs. Similarly, Guglielmino et al. (1995) seek to define which memes (or cultural traits) belong to which cultures, and to work through the evolutionary implications of meme distribution at the societal level. Here we have the meme as artefact/behaviour studied in its own right, without the confusing mentalistic stance that currently plagues human memetics.

8 Criticisms Anticipated

Some may reply to the above by saying:

8.1 That Memes are Only Abstractions

One might argue that, since memes are abstractions, we need not worry overly about their ontological status (de Winter 1984). All one needs are tokens for mathematical analysis. This is unsatisfactory, as mathematical modelling is only of value if the model is a reasonable representation of reality. Outside of quantum physics, scientists are generally constrained by the requirement that their models should mirror nature. Even in quantum theory, mathematicians were only driven to the counter-intuitive by the overwhelming weight of experimental evidence. Memetics should be firmly grounded in reality.

8.2 That Memetics is Still in its 'Mendelian' Stage, and We Will One Day be Able to Identify Memes Directly

Another similar criticism might be that before the discovery of DNA, geneticists had to be content with a highly abstract definition of the gene. Prior to the molecular era, genes were only identifiable in terms of phenotypes. Thus a fly geneticist could only identify the white (*w*) mutant allele, indeed could only infer its very existence, by the observation of white-eyed flies. Likewise, one might argue that the (Dawkins B) Windsor knot meme is only identifiable by observation of Windsor knots in this present era of 'Mendelian' memetics, until we have sufficiently advanced in neurobiology to identify the true, internal, mental, neural configurational, meme, in itself without recourse to the external manifestation - just as we can now identify the white (*w*) mutant allele by DNA sequencing without looking at the flies' eyes at all. This argument fails however, for the following reason.

Recall the thought experiment with 100 individuals and the Windsor knot. The individual with the knowledge of how to tie the knot was able to produce 100 knots while there was still only

one meme (Dawkins B definition) for the Windsor knot. By contrast, in fly genetics, each white eyed fly corresponds to two white (*w*) mutant gene sequences (the allele is autosomal recessive - FlyBase 1998). There is no ambiguity; 100 white-eyed flies equals 200 white (*w*) mutant alleles. But in memetics, we cannot be sure how many Windsor knot memes (Dawkins B definition) were responsible for 100 Windsor knots. Thus the situation in memetics at present is not analogous to the Mendelian era of classic genetics. It is true to say that genes were merely abstractions in those days, but they were a very different kind of abstraction to the meme.

8.3 That All the Above is Inadmissible as it Constitutes an Attack on Memetics

The above two theses, that there can be no population memetics (except in a strictly behaviourist sense) or thought contagion theory, and that memetics cannot be used to study belief states, are bound to cause some consternation within the memetics community. Many may take them as an attack on memetics as a discipline. This is *not* my intention. Rather I see myself as strengthening memetics by preventing its inflation beyond the boundaries of what is acceptable for a scientific field. Population memetics proper (ie. those authors who treat memes as culturally inherited traits) is mostly conducted in a behaviourist manner. Its best empirical results have been achieved when investigators cease attempting to assign memes to individuals and treat them as behaviours occurring within a cultural milieu (Guglielmino et al. 1995).
